

# Characterisation of sericitic alteration at the Taca Bajo porphyry Cu deposit, Argentina

by

Sebastian Benjamin Benavides Kolind-Hansen (B.Sc. Geol. Eng.)

CODES ARC Centre of Excellence in Ore Deposits

Submitted in fulfilment of the requirements for the Master of Economic Geology

University of Tasmania, June, 2017

### **Declaration of Originality**

This thesis contains no material which has been accepted for a degree or diploma by the University or any other institution, except by way of background information and duly acknowledged in the thesis, and to the best of my knowledge and belief no material previously published or written by another person except where due acknowledgement is made in the text of the thesis, nor does the thesis contain any material that infringes copyright.

## Acknowledgements

This thesis wouldn't have been possible without the support received from First Quantum Minerals Ltd. I'd like to begin thanking Mike Christie for constantly supporting my professional development ever since I joined FQM and giving me the opportunity to grow as a geologist. I'd also like to thank Tim Ireland for all the technical and professional guidance and editorial support received regarding this manuscript and all other projects I endeavour into. Markku Lappalainen has been key in allowing me enough flexibility and support at work to be able to get the thesis and courses done while working a full-time job.

I'd also like to thank the FQM team involved in Taca Taca Bajo exploration, in particular Guillermo Almando and Santiago Gigola for the discussions, guidance and feedback received, as well as for taking the time to discuss historical data and regional interpretations.

At Utas, I'd like to thank David Cooke, not only for being a great supervisor and providing thorough edits and observations on the manuscript, but also for always being available to guide me in the right direction during my time there. I'd also like to thank Rob Scott for the immense support throughout the whole Master's programme. I am grateful for the assistance provided by Lejun Zhang, Sebastien Meffre, Leonid Danyushevsky, Ivan Belousov, Jay Thompson, Ayesha Ahmed, Karsten Goemann and Sandrin Feig with the operation of laboratory equipment and processing of data.

## Abstract

The Taca Taca Bajo porphyry Cu deposit contains 2,165 Mt at 0.57% Cu Eq. It is located in the province of Salta, in north-western Argentina. It was emplaced in the back-arc of the Chilean Eocene-Oligocene porphyry belt, and localised by WNW trending cross-arc lithospheric structures. Multiple phases of syn-mineralization Oligocene ( $29.30 \pm 0.57$  Ma) rhyodacite porphyritic intrusives have been recognized, although most of the mineralisation is hosted in the Taca Taca Silurian granite batholith host.

Green sericite has been observed at Taca Taca Bajo to be spatially associated with Cu mineralisation and thought to be part of the phyllitic assemblage, occurring together with white sericite. A combination of petrography, spectrometry, scanning electron microprobe (SEM) and laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS), has shown that the green sericite in Taca Taca Bajo is phengite, and occurs as fine grained, shaggy replacements of pre-existing secondary biotite and orthoclase. White sericite, on the other hand, occurs as a late, pervasive alteration of coarse, bladed muscovite which overprints and destroys all pre-existing alteration and mineralisation. Spectral data suggests that phengite crystallised at higher temperature and pH than muscovite, and is interpreted to be a temporal transition stage between potassic and phyllitic alteration. Chalcopyrite was introduced during the early potassic and phengite alteration phases. The later muscovitic stages were ore-destructive, with chalcopyrite replaced by pyrite and, as the system cooled, a pyrite – bornite – chalcocite – covellite high sulfidation state assemblage.

Phengite has been reported previously in porphyry Cu deposits, typically as an outer, lower temperature alteration mineral. In the case of Taca Taca Bajo, phengite appears to be analogous to sericite – chlorite – clay (SCC) alteration documented elsewhere, with a compositional variation potentially due to the felsic nature of the host rocks. Using systematic spectral measurements and whole rock assay data, it is possible to map the area where phengite has overprinted pre-existing potassic alteration.

# 1. Introduction

## 1.1 Porphyry Copper Deposits

Porphyry deposits are of paramount importance to economic geology, as they host most of the world's copper and much of the molybdenum and gold resources. They are distributed widely across the world, mostly in convergent margin terranes (Sillitoe, 2010). These deposits are formed within and around causative hypabyssal porphyritic intrusions (Proffett, 2009) and typically represent high tonnage and low grade resources (Seedorff et al. 2005; Sillitoe, 2010).

Spatially, porphyry deposits tend to form in clusters within active to waning magmatic arcs; a characteristic clearly demonstrated in the South American Andes (Haschke et al., 2002; Sillitoe and Perelló, 2005; Singer et al., 2005; Sillitoe, 2010). The position of these clusters are inferred to be controlled by structural permeability and world class deposit clusters tend to be related to long-lived cross-arc lithospheric structures (Richards et al., 2001; Gow and Walshe, 2005; Singer et al., 2005; Palacios et al., 2007; Sillitoe, 2010).

Porphyry Cu deposits are also controlled in time by specific tectonic events. Stress changes in the subduction zone are interpreted as catalysts for porphyry ore formation in zones of compression, crustal thickening, uplift and exhumation (Cooke et al., 2005; Sillitoe, 2010). In the case of Andean deposits, these events are related to the onset of different orogenic events (Noble and McKee, 1999) and to the subduction of aseismic ridges or plateaux (Rosenbaum et al., 2005; Hollings et al., 2005), and/or subduction of major seafloor transforms (Richards and Holm, 2013)

Wall rock alteration around major porphyry copper deposits affects several cubic kilometres of rock (Lowell and Guilbert, 1970; Sillitoe, 2010). For this reason, exploration geologists have typically used alteration models to navigate different types of wall rock alteration in the search of the core of the hydrothermal system. Recent work has been focused on understanding distal alteration patterns at trace level geochemical variations (Chang et al., 2011; Cooke et al., 2015; Halley et al, 2015; Wilkinson et al., 2015).

Veins and alteration assemblages are typically zoned within the causative intrusion and encompassing host rocks, and their relation to sulfide abundance and mineralogy (and hence

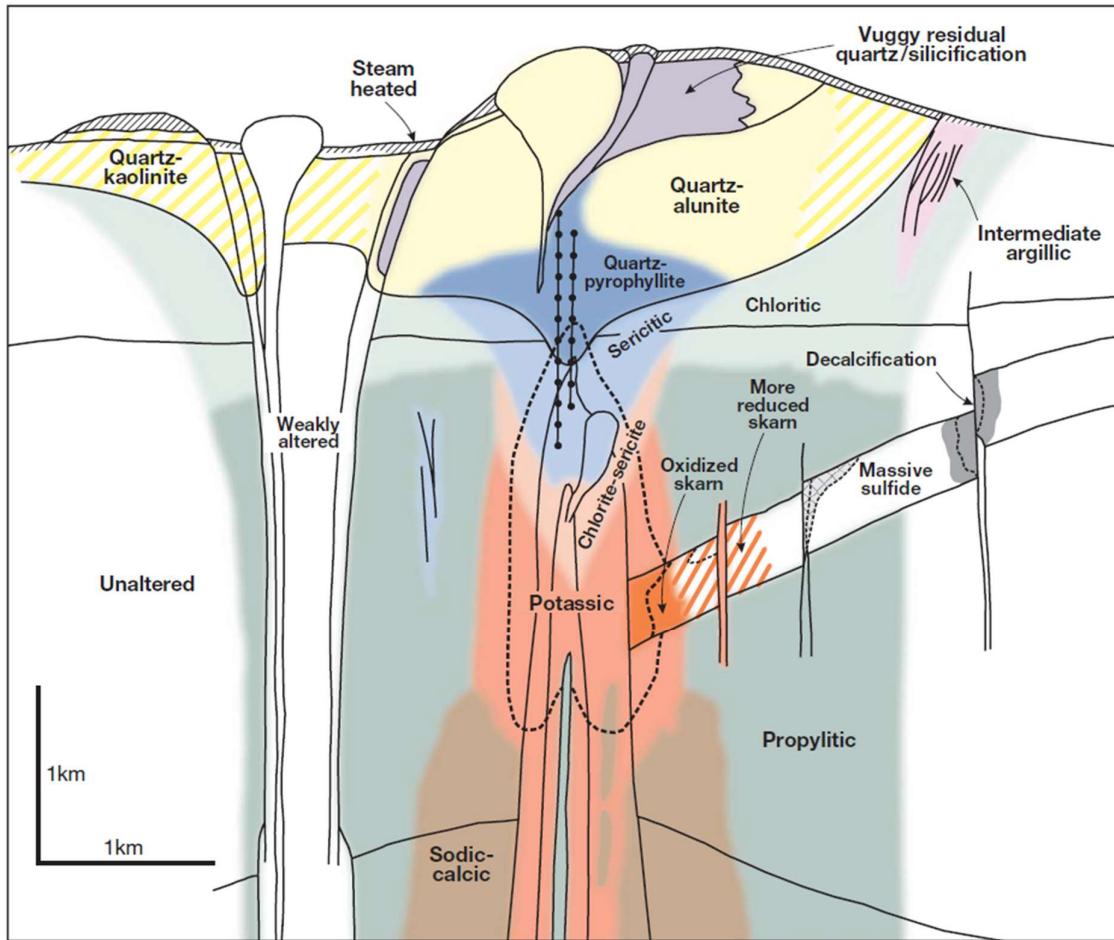

to ore) has been the subject of intense research. Recent detailed descriptions of these features are provided by Seedorff et al. (2005, 2008), Sillitoe (2010), and references therein. The alteration model provided by Sillitoe (2010; Fig. 1.1) shows a deep, barren sodic calcic alteration phase, which transitions upwards to a core potassic alteration (main ore contributor) and laterally into propylitic alteration, characterised by chlorite, epidote, albite and actinolite. During the waning stages of the porphyry hydrothermal system these early assemblages are overprinted by cooler, acid fluids, which generate phyllosilicate minerals that define a “phyllitic” alteration zone. This zone is in some cases related to ore, but is much more commonly barren (e.g. Sillitoe and Gappe, 1984).

## 1.2 Sericitic Alteration in Porphyry Copper Deposits

Phyllitic alteration was described by Lowell and Guilbert (1970) as an overprinting alteration assemblage consisting of quartz, sericite, pyrite, hydrated micas, minor chlorite and trace rutile. This alteration assemblage, or variations of it defined by the presence of phyllosilicate minerals has since been recognised as a fairly consistent aspect of the zoned alteration that overprints and surrounds the potassic altered core of porphyry copper hydrothermal systems, though there are substantial variations in terms of the metal input and/or destruction patterns in different deposits (Lowell and Guilbert, 1970; Rusk et al., 2008; Sillitoe, 2010; Perelló et al., 2012). Phyllitic alteration will form at temperatures between 550° C to 250° C, within the muscovite and illite stability field (Seedorff et al., 2005). Sillitoe (2010) divides this acid overprint into two members: sericite – clay - chlorite (SCC) alteration and sericitic alteration (phyllitic).

SCC alteration is common to the upper regions of ore bodies and is commonly related to Cu grades, as it is considered the upward continuation of potassic alteration. This alteration is characterised by replacement of mafic minerals to chlorite and feldspars to sericite, together with pyrite and chalcopyrite deposition (Sillitoe, 2010). Quartz - hematite (after magnetite) – chalcopyrite - pyrite veins with sericite - chlorite halos are common in this alteration assemblage, and they are considered to be the upward continuation of potassic early, dark micaceous veins (Rusk et al., 2008).

Phyllitic alteration overprints potassic and SCC alteration, typically extending from the outer edge of the potassic ore zone, defining a pyrite-rich halo adjacent to propylitic alteration (Sillitoe, 2010). It is characterised by widespread, pervasive white sericite that occurs as halos and coalesced halos to quartz - pyrite veinlets, and typically replaces all pre-existing silicates and sulfides (Lowell and Guilbert, 1970; Sillitoe, 2010).

*Figure 1.1: Schematic, generalised alteration model for porphyry Cu deposits. This model is for a telescoped system, but the sericitic and chlorite-sericite overprint on potassic and propylitic alteration is also common without a significant degree of telescoping. (Sillitoe, 2010)*

Less common grey-green sericitic assemblages have been documented in different deposits as part of the phyllitic alteration assemblage. ‘Green sericite’ is somewhat of a bucket terminology in the exploration community. When described and studied, this term encompasses several different textures, compositions and relationships to ore. In Chuquicamata, green sericite occurs within the ore zone and is related to Cu sulfides

(Ossandon et al., 2001); while at Los Pelambres, it is found in the outer phyllitic zones, has a phengite composition and only a minor relationship to Cu sulfides (Perelló et al., 2012). Alva (2011) reported both phengitic green sericite distal to the main ore zone and green-white sericite - chlorite alteration as halos to ore bearing veins in the Highland Valley district. The porphyry model of John et al. (2010) suggest a distal phyllitic assemblage of Fe-rich sericite (phengite) which is also commonly logged as green sericite. This later model matches the systematic increase in 2200 wavelength spectral absorption feature in white micas outboard of porphyry deposits described by Halley et al. (2015).

As the fluids responsible for sericitic alteration cool down, acidity and sulfidation state increases, hence the later stages of sericitic alteration might be stable with high sulfidation sulfide assemblages such as bornite – pyrite – covellite - digenite (Fig. 1.2; Sillitoe, 2010), whereas earlier sericitic assemblages can be stable with respect to chalcopyrite - pyrite.

### 1.3 Sericite Description and Chemistry

Sericite is field terminology for fine grained K-bearing mica and clay (Seedorff et al., 2005), particularly the muscovite compositional variation. It is commonly used given the difficulty of differentiating fine grained muscovite, phengite, illite and paragonite in the field with a hand lens.

Micas are composed of stacked layers of octahedral sheets bound by tetrahedral sheets in a “t-o-t” arrangement (Fig. 1.3; Klein and Dutrow, 2008). The muscovite formula is  $KAl_2(AlSi_3O_{10})(OH)_2$ , where the  $K^+$  cation site is located between each “t-o-t” layer (Deer et al, 2003; Alva, 2011). When Si substitutes for Al in the tetrahedral sites of the  $SiO_5$  sheets, the “t-o-t” layers become more neutral and lack the need of an interlayer cation, forming clays like talc ( $Mg_3Si_4O_{10}(OH)_2$ ) or pyrophyllite ( $Al_2Si_4O_{10}(OH)_2$ ; Klein and Dutrow, 2008).

Illite ( $((K,H_3O)(Al,Mg,Fe)_2(Si,Al)_4O_{10}[(OH)_2,(H_2O)])$ ) is characterised by random, partial substitution of Al by Si in the tetrahedral site, where occasional interlayer cations sites are occupied and molecular water is introduced, producing an alkali-deficient mineral with

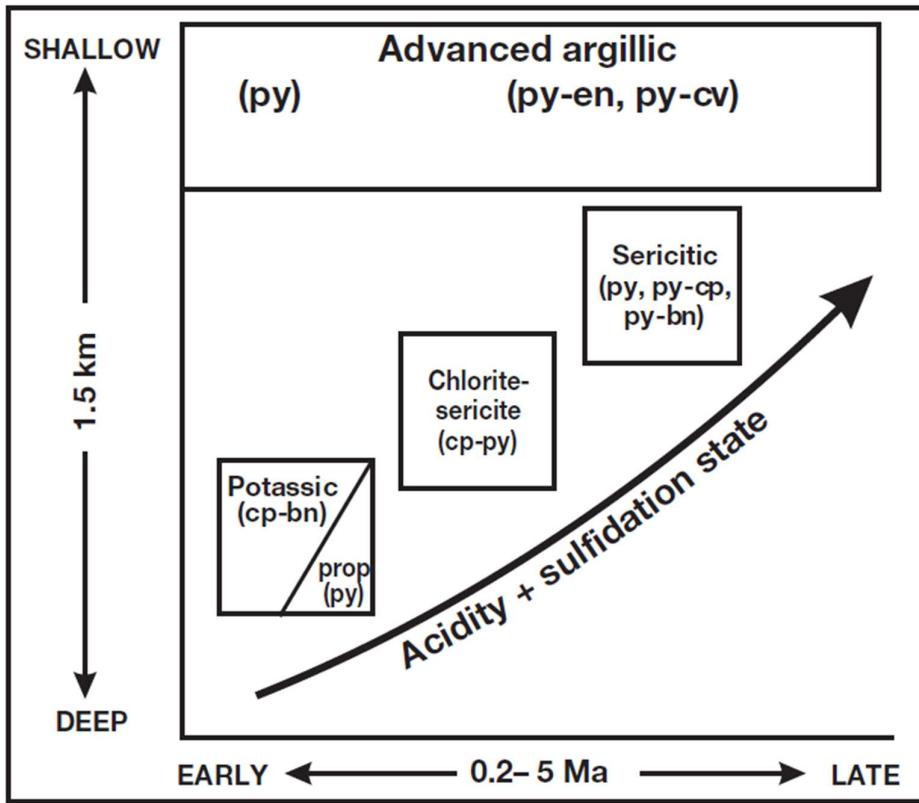

Figure 1.2: Schematic representation of fluid characteristics and alteration products in the life of a single porphyry system. Note the SCC (sericite-chlorite) alteration is stable with chalcopyrite-pyrite and sericitic alteration is stable with regard to pyrite, minor chalcopyrite and high sulfidation assemblages (Sillitoe, 2010).

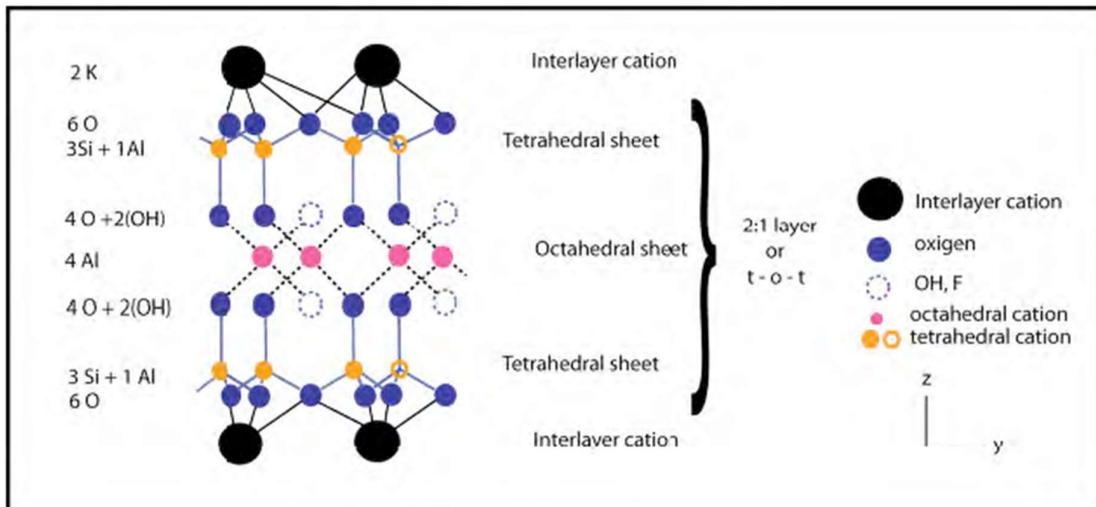

Figure 1.3: Ideal muscovite arrangement. Note the “t-o-t” sheets typical of phyllosilicates, in the case of muscovite bounded by K as an interlayer cation (Alva, 2010; after Deer et al., 2003).

properties of both clay and mica group minerals (Meunier and Velde, 2004; Klein and Dutrow, 2008).

Typical substitutions in the muscovite composition are Na, Rb and Cs for the K<sup>+</sup> interlayer cation site, Mg, Fe<sup>2+</sup>, Fe<sup>3+</sup>, Li, Mn, Ti and Cr for the octahedral Al site and F for the OH site (Klein and Dutrow, 2008; Table 1.1). These element substitutions may occur due to the breakdown of pre-existing muscovite or due to a geochemical input from the pre-existing mineral being altered to sericite. Since different sericite species are stable at different pH and temperature conditions, general paragenetic interpretations can be made.

Potassium feldspar is stable at higher pH and temperature conditions than muscovite (Fig. 1.4). As the hydrothermal system cools and becomes more acid, feldspars can be replaced by muscovite and other K-bearing micas, together with quartz. On the transition towards intermediate argillic alteration, illite is stable at 300-250° C (Seedorff et al., 2005; Alva, 2011).

## 1.4 Objective

Green sericite has been used at the Taca Taca Bajo porphyry Cu deposit, Argentina, to describe a grey-green mica that occurs commonly within the ore zone. This particular sericite type shows a strong correlation with chalcopyrite and chalcopyrite - pyrite assemblages and coexists with a white sericite overprint of potassic alteration. Two hypotheses were presented by the company currently exploring the property, First Quantum Minerals (FQM), for the nature of the green sericite. The first hypothesis is that it is of phengite composition and formed synchronous with white sericite, which would be in agreement with the observations made at Los Pelambres (Perelló et al., 2012) and with observations made by John et al. (2010). The disagreement lies that in both of these cases, phengite is characterised as a distal, lower temperature mica that is not related to ore deposition, whereas the opposite relationship is in fact observed in Taca Taca Bajo. The second hypothesis is that the green sericite is a mixture of fine grained muscovite and chlorite, as part of a transition from potassic to phyllitic

Structure	Substitution	Species	Formula	Remarks
Interlayer cation: K <sup>+</sup>	K <sup>+</sup> = Na <sup>+</sup>  K <sup>+</sup> = Ca <sup>2+</sup> K <sup>+</sup> = Ba <sup>2+</sup>  K <sup>+</sup> = Rb <sup>+</sup> , Cs <sup>+</sup> , Sr <sup>2+</sup> , Ti <sup>3+</sup>  K <sup>+</sup> = NH <sub>4</sub> <sup>+</sup> K <sup>+</sup> = □	Paragonite  Margarite Oellacherite  Illite	NaAl <sub>2</sub> □AlSi <sub>3</sub> O <sub>10</sub> (OH) <sub>2</sub> K<0.15; Ca<0.11  CaAl <sub>2</sub> □(Al <sub>2</sub> Si <sub>2</sub> O <sub>10</sub> (OH) <sub>2</sub> [Ba <sub>0.5</sub> (Na,K) <sub>0.5</sub> ]Al <sub>2</sub> (Si <sub>2.5</sub> Al <sub>1.5</sub> O <sub>10</sub> ) (OH) <sub>2</sub>  Rb may be up 1%; Rb may be up to 5%; Sr reported 0.0025-0.013%  Rare; the presence of hydronium is not well documented. Table 1.1: Typical substitutions into the muscovite crystal structure and their associated phyllosilicate species. Redrafted from Alva (2010); after Bailey (1984), Muñoz (1984), Guidotti (1984), Deer et al. (1992), Dahl et al. (1993), Guidotti and Sassi (1998), Deer et al. (2003) and Rieder (2001).

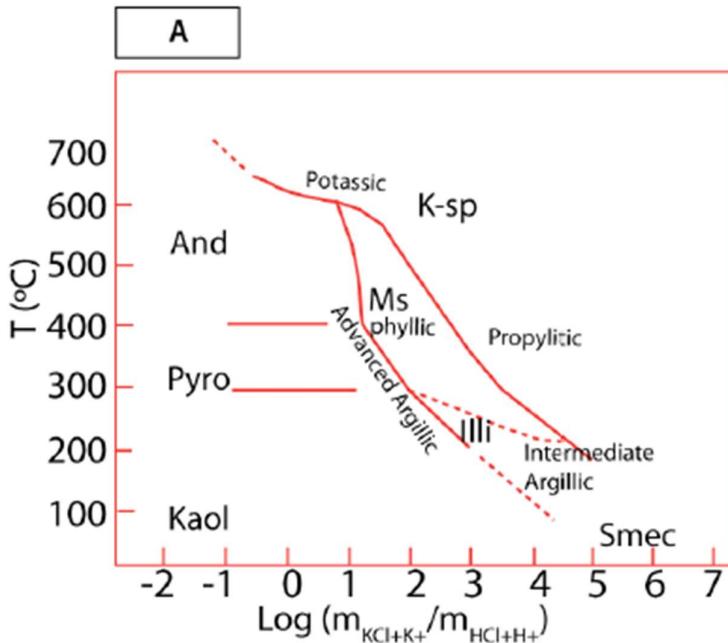

Figure 1.4: Phase diagram at 1kbar, showing the stability fields for different silicates with changes in temperature and pH. Potassic alteration occurs at the K-feldspar stability field and as the system cools, muscovite becomes stable and replaces K-feldspar and plagioclase. If fluids become buffered by wallrock interaction, they will transition to intermediate argillic as they cool, if they are not buffered, they will eventually become stable with advanced argillic alteration. Redrafted by Alva (2010) after Seedorff et al. (2005).

alteration (Fig. 1.2). Prior to this study, this was the main working hypothesis at Taca Taca Bajo, although the chlorite had not been identified through petrography or other means.

The first objective of this study is to understand compositional and textural differences between the logged green and white sericite and their relationships with potassic alteration and main stage mineralisation. It is hoped that this will allow for better understanding of the ore controls at Taca Taca Bajo, and also for development of a more accurate paragenetic sequence.

The second objective is to use petrographic analysis to extrapolate to material classification at the deposit scale. It may be that a better understanding on sulfide and silicate speciation, and relationships to gangue mineralogy may prove helpful when the project reaches a production stage. This study therefore combines two-meter interval assay data with point

spectrometry data with trace element geochemistry to model different sericite appearances at a deposit scale.

The final objective of this study is to contribute to the current understanding of the grey-green sericite reported by Sillitoe (2010) which has been reported in several deposits but within different regions in the deposit model. This further understanding will provide future explorers with more information to make accurate interpretation when encountering green sericite in porphyry copper deposits.

## 2. Taca Taca Bajo Porphyry Copper Deposit

### 2.1 Location

The Taca Taca Bajo deposit is located in the Salta province, 230 kilometres west of the city of Salta, in the Puna region of north-western Argentina (Fig. 2.1). The deposit is located 25 kilometres from the Chilean border and roughly 150 kilometres east-southeast of the La Escondida porphyry Cu deposits in Chile. The closest town and accommodation is Tolar Grande, which is located on the opposite edge of the Salar de Arizaro, 35 kilometres east of Taca Taca Bajo.

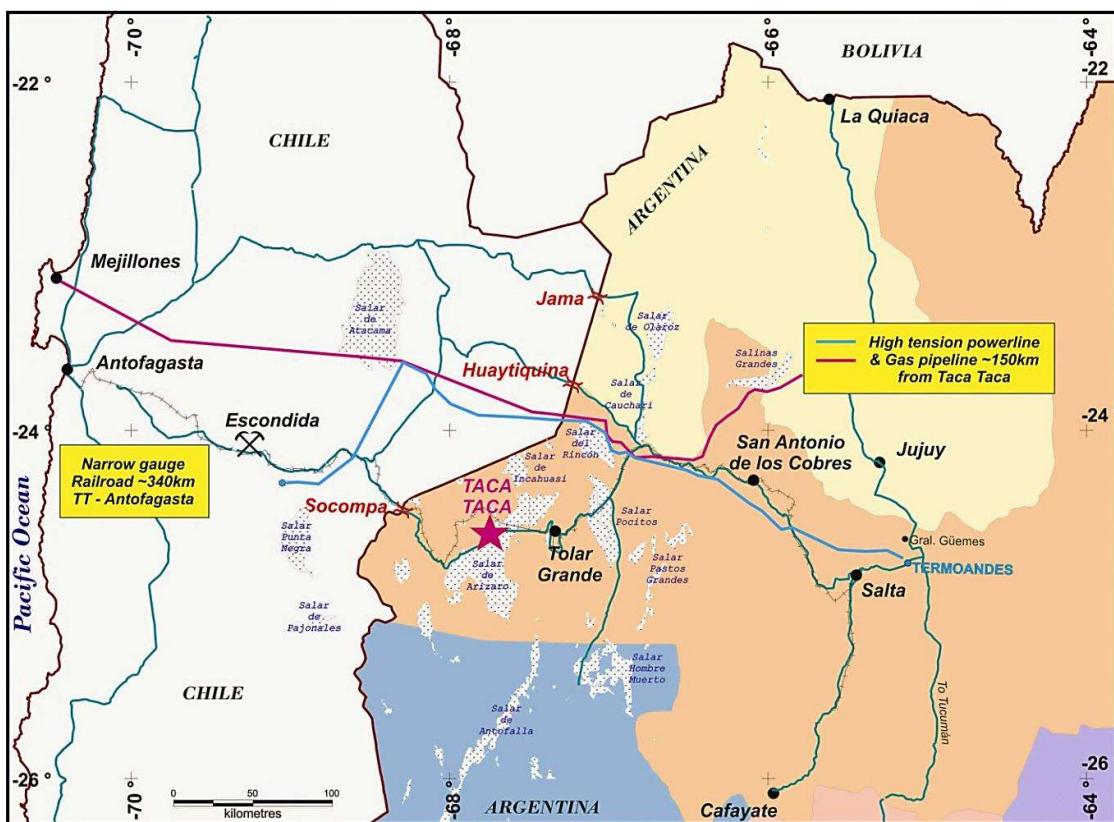

Figure 2.1: Location of the Taca Taca District with relation to major cities and deposits in Argentina and Chile (Scott et al., 2013).

## 2.2 Exploration History

The porphyry deposit was discovered by Fabricaciones Militares, a state-owned company, in 1967 and has since been explored by Falconbridge Argentina S.A., Gatro Argentina Minera S.A., BHP Minerals, Corriente Resources, Rio Tinto, Global Copper, Lumina Copper and its current owner, First Quantum Minerals Ltd (Almadox, 2015). Though the project was drilled by many companies through that time, geological models, adverse commodity prices and varying exploration strategies had a strong influence on the lack of definition of an economic resource at Taca Taca Bajo until 2010, when Lumina Copper had enough economic intercepts to plan a starter pit and pursue definition of the current sulfide indicated resource of 2,165 Mt at 0.57% CuEq (0.44% Cu, 0.08 g/t Au, 0.013% Mo; cut-off grade of 0.3%; Scott et al., 2013).

Overall, Taca Taca Bajo has a modern exploration history spanning at least 45 years, during which time 163,537 meters have been drilled in 400 drill holes (Table 2.1; Almadox, 2015).

COMPANY	YEAR	TARGET	ACTIVITIES	TOTAL METRES DRILLED
FABRICACIONES MILITARES	1967	Cu Porphyry	First mapping

Table 2.1: Exploration history at Taca Taca Bajo (Almadox, 2015).

## 2.3 Regional Geology and Structural Setting

### 2.3.1 Tectonic and Metallogenic Setting

The Oligocene porphyry Cu deposits and occurrences in northwestern Argentina are related to the Eocene-Oligocene metallogenic belt of Chile and Peru (Fig. 2.2). An eastern bulge was included in the metallogenic belt by Sillitoe and Perelló (2005) - this was specifically drawn to incorporate Taca Taca Bajo within the magmatic arc. Mineral occurrences in the Puna region occur along WSW-trending lineaments, which are characterised by volcanic breakouts of the main arc that are inferred to have utilised lithospheric-scale cross arc structures (Alonso and Viramonte, 1987; Richards et al., 2000; Chernicoff et al., 2002). Alonso and Viramonte (1987) mapped these lineaments for Miocene volcanic strata and showed the characteristics that defined them (Fig. 2.3). Note that Taca Taca Bajo is not located within one of these lineaments. The structure controlling the emplacement of Taca Taca Bajo does not seem to have been active in the Miocene.

These cross-arc structures has been inferred to control porphyry emplacement by providing crustal permeability that facilitated magma ascent inboard of the active arcs in Chile, into their back arc in Argentina (Alonso and Viramonte, 1987; Richards et al., 2000; Chernicoff et al., 2002). Gigola (2015) interpreted a more subdued WNW structural corridor that connects Taca Taca Bajo and Socompa mineralised centres to the Eocene-Oligocene belt of Northern Chile (i.e. Escondida-Zaldivar cluster). In agreement with this interpretation, Taca Taca Bajo is interpreted to be in the back-arc of the Chilean Eocene-Oligocene porphyry belt (Almandoz et al., 2008), and its location was controlled by a WNW lithospheric cross-arc structure that did not influence later Miocene volcanism.

The location of late Cenozoic magmatism and porphyry Cu deposits east of the magmatic arc (e.g., Bajo de la Alumbra in the Sierra Pampeanas region) has been interpreted to be linked to segments of flat-slab subduction due to the subduction of seamount chains and oceanic plateaus, forming focused, isolated igneous centres (Proffett, 2003). This is potentially also the case for Oligocene magmatism in the Puna region also.

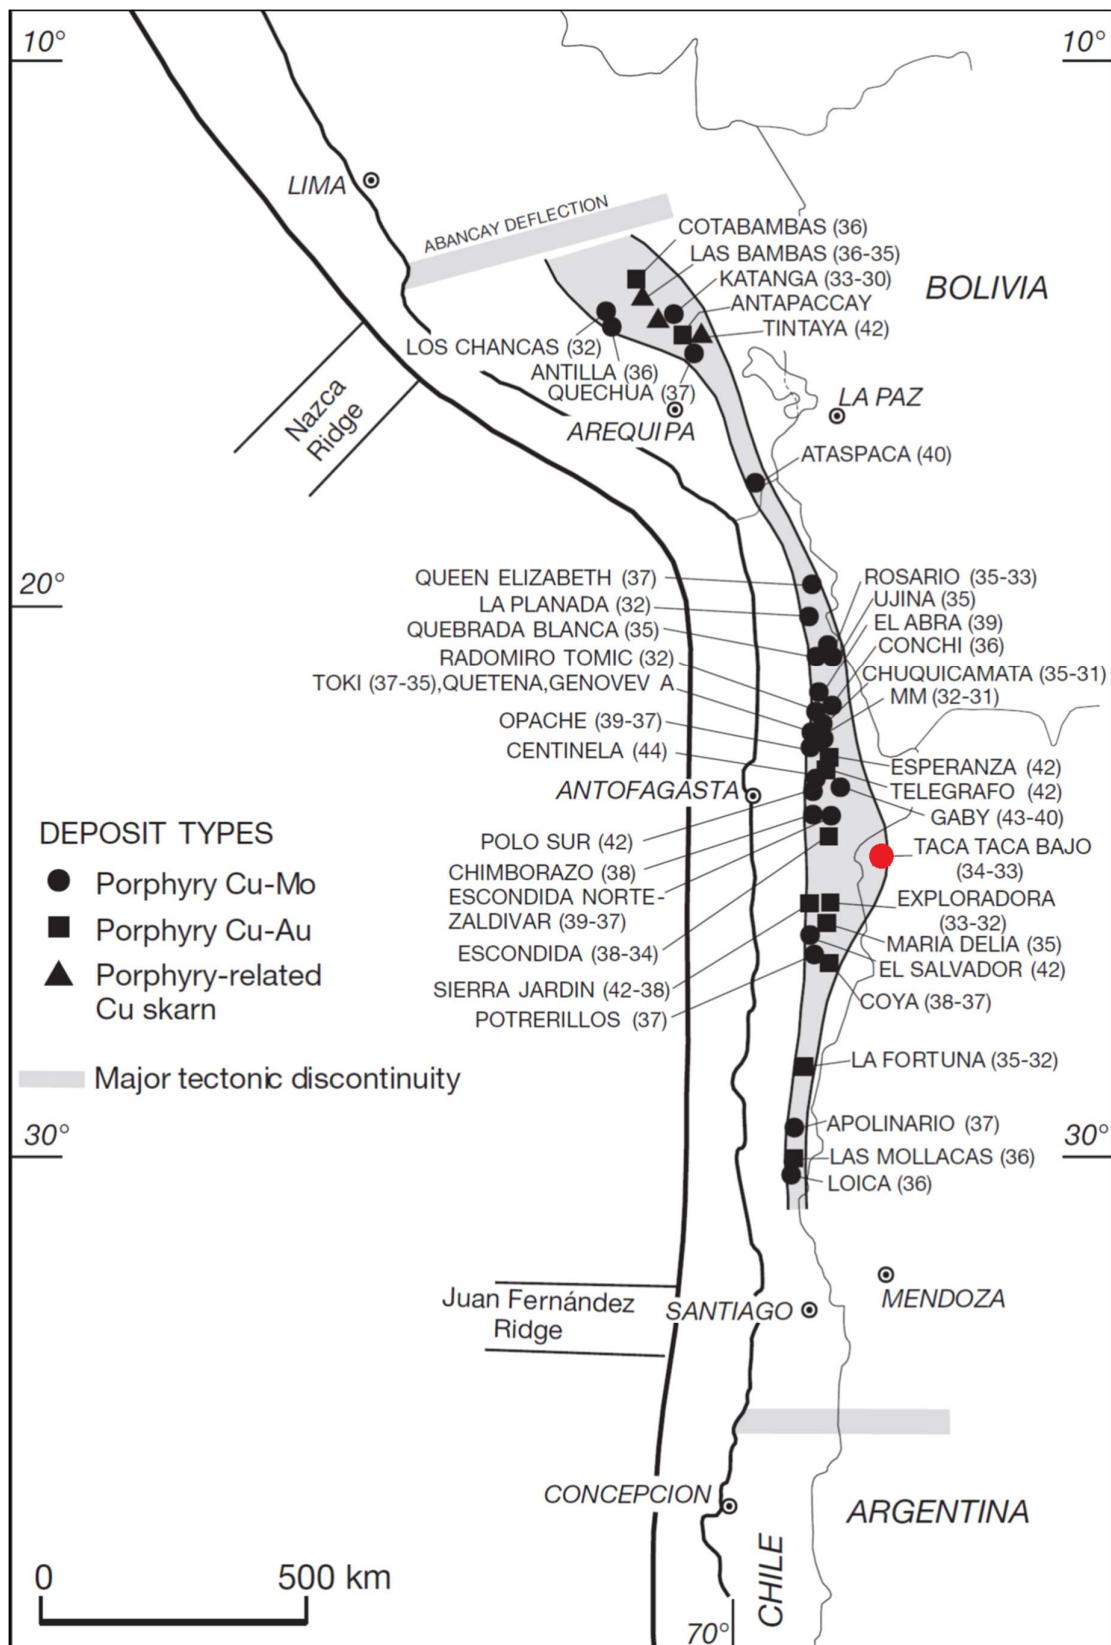

Figure 2.2: Eocene to early Oligocene belt of Northern Chile and Southern Peru, showing the location of Taca Taca Bajo in relation to contemporary deposits. From Sillitoe and Perelló (2005).

From Alonso and Viramonte (1987).

### *2.3.2 Geology of the Puna Region*

The Puna region, host to the Taca Taca Bajo orebody, is a desert on a high elevation (3,000 – 6,000 masl.) depression. This back-arc basin is bound by high angle reverse faults (Turner, 1972). It is flanked on its western side by the volcanic Western Cordillera and on its eastern margin by the Palaeozoic Eastern Cordillera (Alonso and Viramonte, 1987). Prior to its uplift in the Tertiary, this region accumulated sediment as a continental back arc basin since the early Carboniferous. Prior to the Carboniferous, the region underwent continental growth by island arc accretion, and at least two cryptic arc terranes are interpreted to have accreted to the western margin of this part of Gondwana between the Cambrian and Silurian (Ramos and Aleman, 2000).

Outcrops of crystalline basement in the region are scarce and discontinuous. They consist of Precambrian to early Cambrian, medium to high grade metamorphic and metasedimentary rocks, including slates of the Puncoviscana Group and quartzites of the Mesón Group (Fig. 2.4; Turner, 1960; Mangano and Buatois, 2004). The Ordovician was a period of active sedimentation throughout the region, where clastic continental and marine sediments were deposited, together with minor submarine volcanic flows. Some of these units now display low grade metamorphism related to the emplacement of later stocks. Three main calc-alkaline batholiths intruded the previously described strata during the Ordovician-Silurian, one of which is the Taca Taca granite batholith, the host to Taca Taca Bajo (Fig. 2.4; Salfity et al., 1975; Alonso and Viramonte, 1987 and references therein).

Even though there is not much record of later Palaeozoic sedimentation in the area, there are some red sandstones and conglomerates that crop out in the Northern half of the Puna region, including the Cerro Oscuro and Arizaro formations (Fig. 2.4). Along strike to the south and north, the upper Palaeozoic to Mesozoic is marked by the development of deep intracontinental basins in which thick packages of clastic and lesser carbonate sediment accumulated (Salta and Neuquén basins; Alonso and Viramonte, 1987).

There is a marked angular unconformity between all rock units described above, and strata that formed from Tertiary sedimentation and volcanism. Above the unconformity there is a prominent sequence of red sandstones and conglomerates that were deposited during the Eocene. These are overlain by a sequence of evaporites, mudstones and minor intermixed

pyroclastic deposits of mostly Oligocene age, the thickness and composition of which varies considerably along strike. Both these sequences are bulked into the Pastos Grandes group (Fig. 2.4; Schwab, 1985; Alonso and Viramonte, 1987)

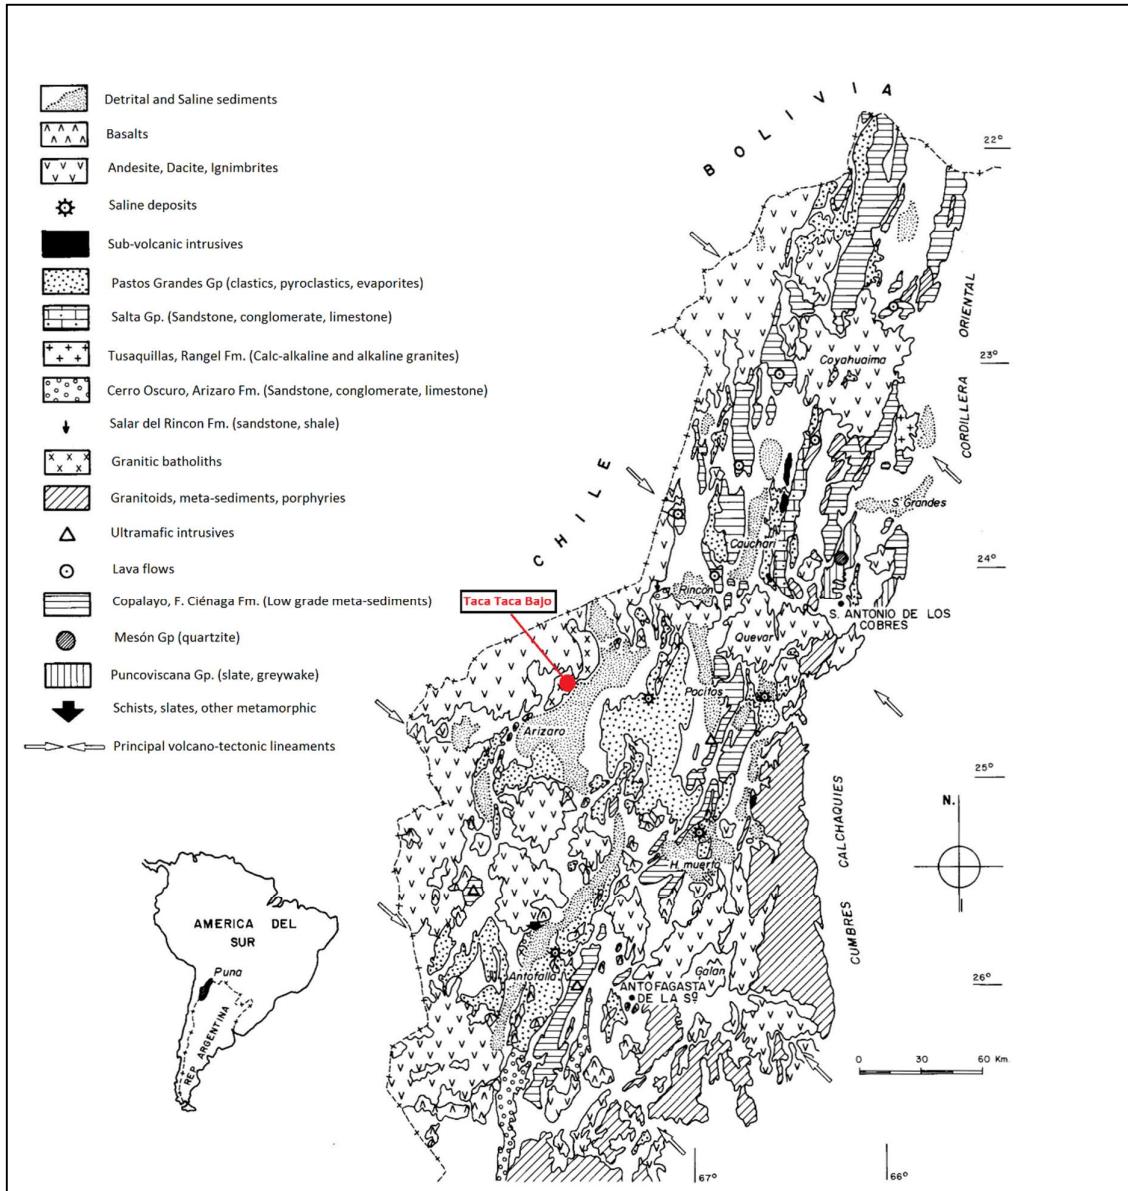

Figure 2.4: Geology of the Puna region showing the location of Taca Taca Bajo, Modified from Alonso and Viramonte (1987).

From the late Oligocene to the Pliocene, voluminous volcanism occurred along the western edge of the Puna, with volcanism extending in linear arrays ESE across the high plateau. Andesite flows, dacite domes, caldera-related ignimbrites and other volcanic features are common in Upper Oligocene to Pliocene stratigraphy of the region (Fig. 2.4). Epiclastic

sedimentation occurred in between these volcanic domains, with accommodation space inferred to have been generated in basins bound by cryptic cross-arc structures. Overall the Tertiary was characterised by rapid shortening and changes in the compressional stresses due to the Inca and Quechua orogenies, in the Eocene-Oligocene and late Miocene, respectively (Salfity and Marquillas, 1994; Sandeman et al., 1995; Oncken et al., 2006). The temporal episodicity of porphyry copper deposit formation has been argued to be controlled by these changes in stress regimes (e.g., Cooke et al., 2005).

During the Quaternary, sedimentary basins were reactivated and locally derived clastic sediments and evaporites accumulated in salt flats (including the Salar de Arizaro, adjacent to Taca Taca Bajo). Localised mafic volcanism also occurred in some regions of the Puna during this time (Alonso and Viramonte, 1987).

## 2.4 District Geology

The geology of the Taca Taca district is dominated by igneous rocks. No true basement is observed in the district, although the oldest units known (Silurian granites, aplites and dolerites of the Taca Taca batholith; Sillitoe, 2008), are regionally distinctive and represent a local basement structurally juxtaposed against younger rocks. The most voluminous package of rocks comprises abundant Permian dacitic volcaniclastic and lesser volcanic sandstones and siltstones. Minor Permian rhyolite dykes intruded the batholith in the vicinity of the Taca Taca Bajo deposit, but are not common in the district. Approximately 5 kilometres northwest of Taca Taca Bajo is Taca Taca Alto, a Permian high sulfidation alteration system ( $257 \pm 18$  Ma; K-Ar on whole rock rhyodacite porphyritic stocks; Zappettini and Blasco, 1998) that was related to Permian magmatism.

Pre-mineral Oligocene dacite to rhyolite volcanic complexes and dykes are inferred to unconformably overlie and intrude Palaeozoic lithologies respectively, but geochronological constraints on these units are weak. Their extent is interpreted to extend throughout most of the covered region (Wood et al., 2015). Volumetrically minor porphyritic rhyodacite dykes (discussed in section 2.4) and rhyolite dykes intruded the Silurian granite.

The other major lithological package in the Taca Taca district are fresh, recent felsic to mafic volcanic flows and complexes which drape over all pre-existing rock types and, together with quaternary colluvium and salt flats, conceal the geology relevant to Oligocene mineralisation. A revised district map was produced by Wood et al. (2015; Fig. 2.5).

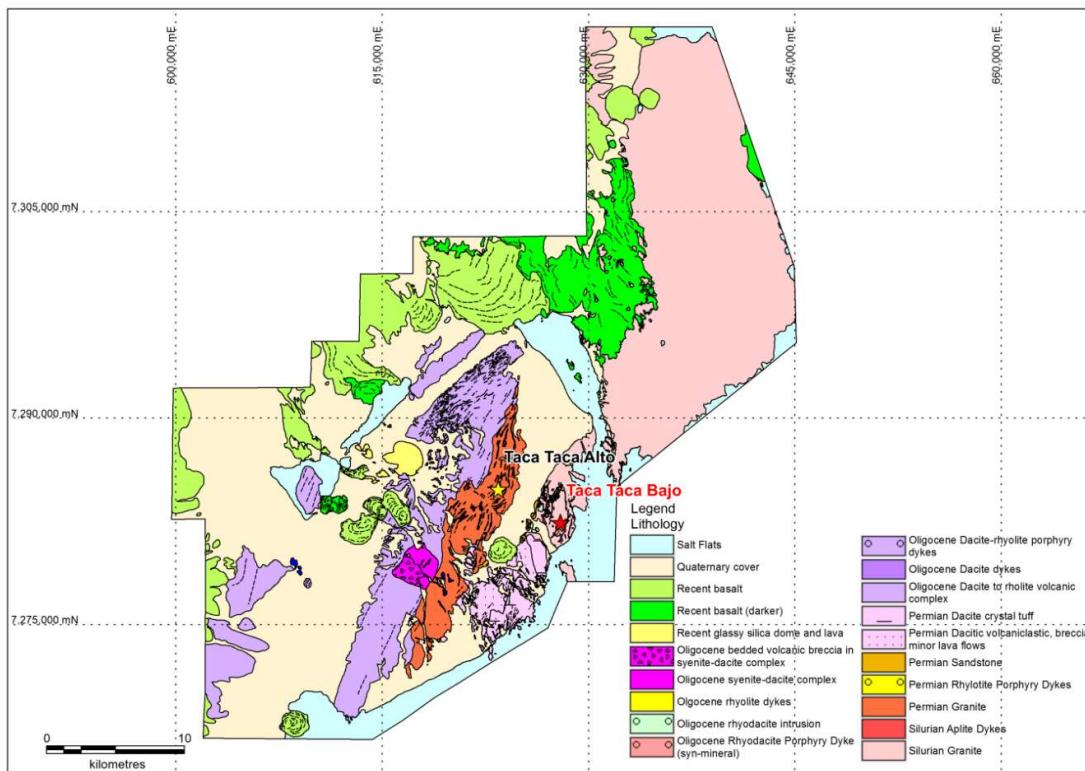

Figure 2.5: Geology of the Taca Taca District (Wood et al., 2015).

## 2.5 Local Geology

### 2.5.1 Lithology

The Taca Taca Bajo porphyry deposit is hosted by the Silurian Taca Taca Batholith. This intrusion is a medium to coarse grained, equigranular, biotite and hornblende-bearing, plagioclase – orthoclase – quartz granite to granodiorite batholith (Fig. 2.7a; Chavez, 2008; Cornejo, 2008; Tripp 2015; Waechter et al., 2015). The batholith was intruded by aplite dykes (Fig. 2.7b) and minor dolerite dykes (Fig. 2.7c), interpreted to be part of the waning stages of batholith emplacement (Sillitoe, 2008). Permian ( $262.4 \pm 2.3$  Ma; U-Pb from zircons, Lumina Copper internal report, 2013), sub-vertical, north-striking rhyolite dykes (Fig. 2.7d) also cut

the Silurian batholith. These dykes have porphyritic textures, with coarse, round quartz phenocrysts in a silicic groundmass and are locally spherulitic (Waechter et al., 2015).

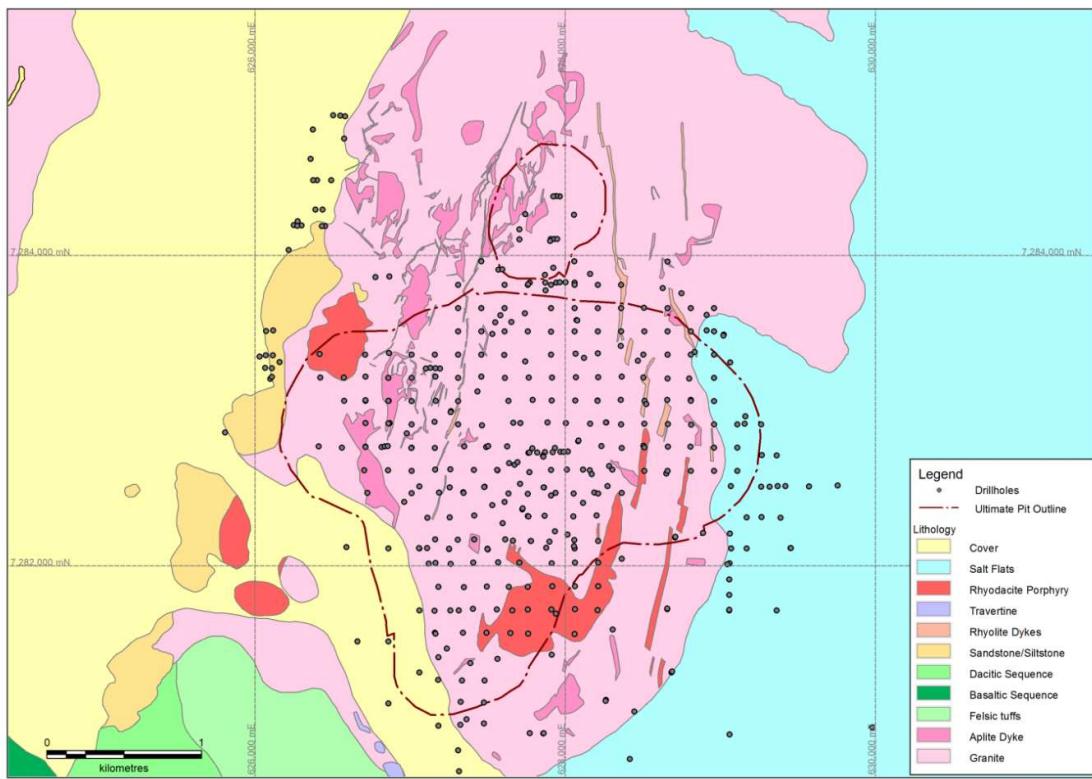

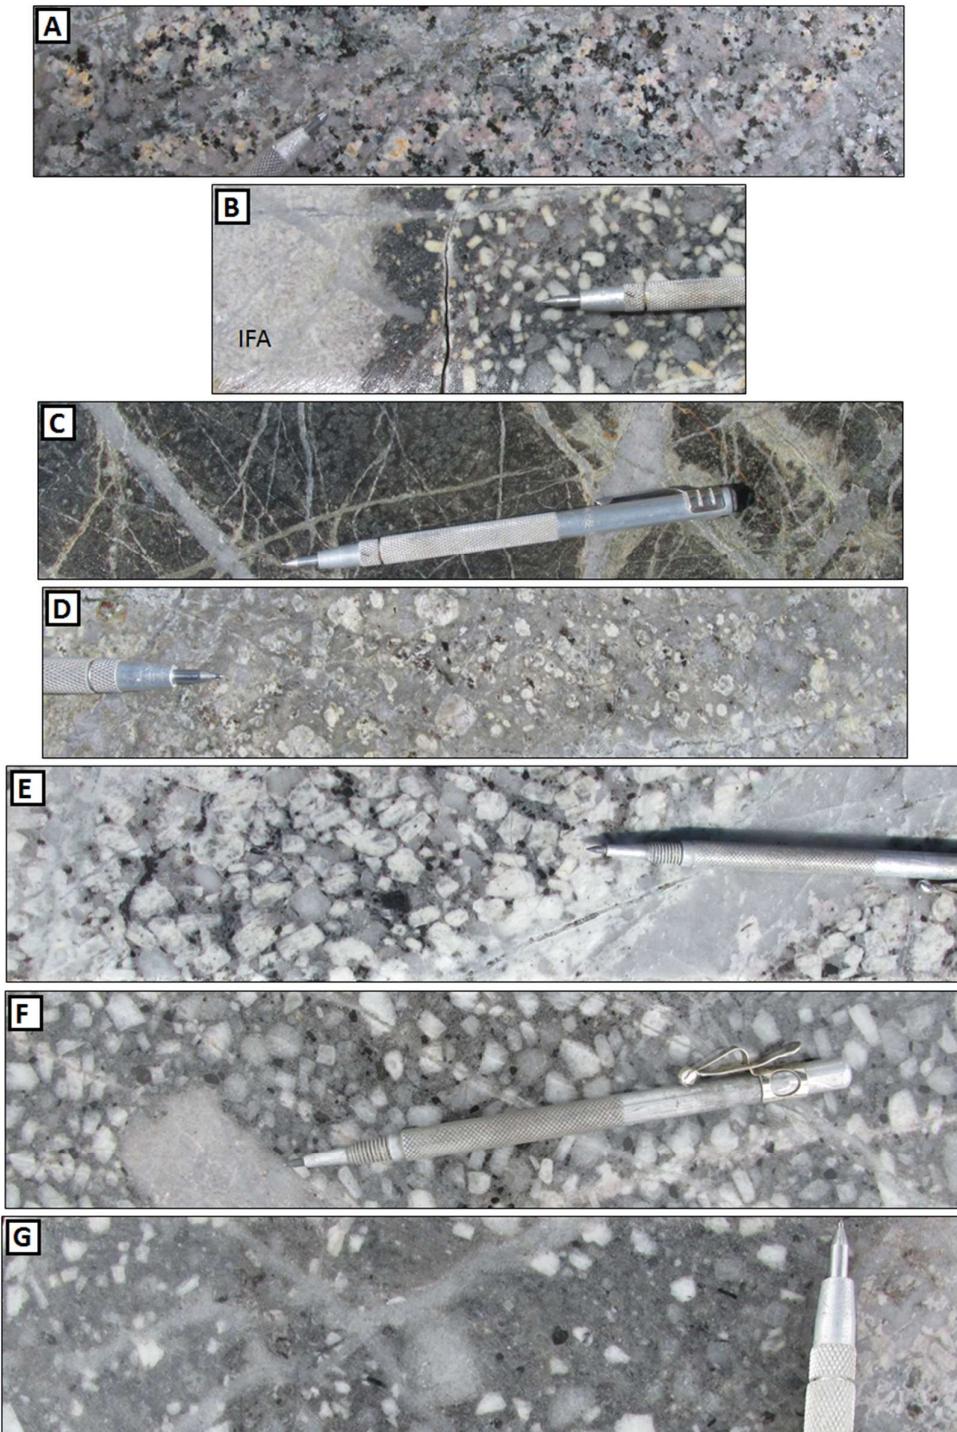

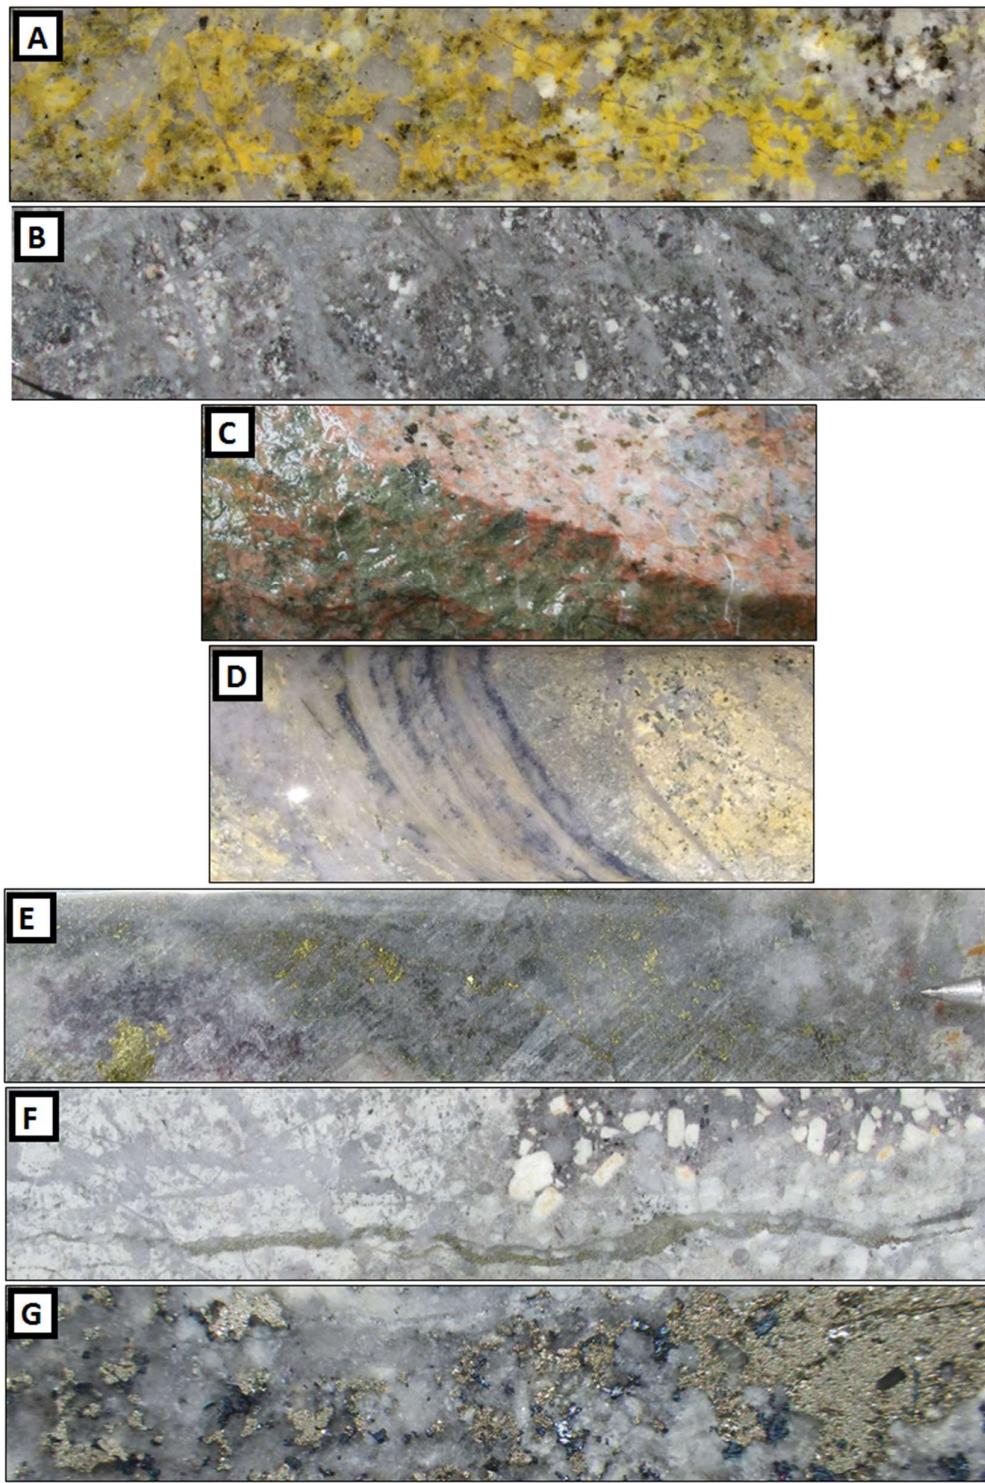

Figure 2.6: Geological Map of the Taca Taca Bajo deposit, modified after Wood et al. (2015).

Three textural variations of Oligocene, syn-mineralisation rhyodacite porphyries have been recognized at Taca Taca Bajo ( $29.30 \pm 0.57$  Ma; U-Pb from zircons; Gigola, 2008). The B1 porphyry is a rhyodacite with coarse porphyritic texture defined by plagioclase and quartz phenocrysts in a shreedy, secondary biotite groundmass (Fig. 2.7e). The B2 porphyry is also early-mineralisation (Fig. 2.7f), but it is distinguished from the B1 porphyry in that it is slightly less crystal-crowded. The late-mineralisation B3 porphyry has similar phenocryst compositions to B1 and B2, but has a less crowded porphyritic texture in an aplitic to secondary biotite-rich groundmass (Fig. 2.7g; Tripp, 2015a; Waechter et al., 2015).

There are no Oligocene post-mineral intrusions in the Taca Taca Bajo project area.

**Figure 2.7: Lithologies of the Taca Taca Bajo deposit.** A) Coarse grained, equigranular Silurian Taca Taca Granitic Batholith; B) Fine grained aplitic dyke truncated by rhyodacite porphyry; C) Silurian dolerite dyke host rock to Oligocene veining and mineralisation D) Permian rhyolite dykes; E) Syn-mineral crowded, coarse grained porphyritic rhyodacite with feldspar and quartz phenocrysts in biotite rich groundmass cut by barren quartz veins and minor quartz-sulfide-sericite vein. F) Syn-mineral moderately crowded, coarse grained feldspar-quartz rhyodacite porphyry with aplite xenoliths. G) Late-mineralisation rhyodacite porphyry with open porphyritic texture of coarse feldspar and quartz phenocrysts in a felsic and shreddy biotite groundmass. Photographs from Waechter et al. (2015).

B) Shaggy biotite potassio alteration in groundmass of rhyodacite porphyry, cut by barren quartz vein stockwork. C) Epidote vein in granite batholith from distal propylitic alteration. D) Quartz-molybdenite banded vein. E) Pervasive green sericite and chalcopyrite with anhydrite patched in ore zone. F) Quartz-pyrite vein with sericite halo rhyodacite porphyry-aplite contact with barren quartz veins G) High sulfidation overprint of pre-existing sulfides with white sericite alteration. Photographs from Waechter et al. (2015).

### 2.5.2 Veining, Alteration and Mineralisation

The inter-mineralisation porphyritic rhyodacite intrusives and directly adjacent granite show intense potassic alteration, with disseminated biotite in the groundmass (Fig. 2.8a) and weak to strong orthoclase flooding (Fig. 2.8b) and phenocryst replacements (Tripp, 2015a). This potassic core shows weak to moderate development of barren quartz veins and transitions towards thick banded, quartz - molybdenite veins (Fig. 2.8d; Benavides, 2015). Only minor bornite and chalcopyrite is observed and this zone is economically insignificant (Fig. 2.9), but Re-Os geochronology on molybdenite from this vein stage yielded an age of  $29.0 \pm 0.2$  Ma (Gigola, 2008) within analytical uncertainty of the age determinations for the rhyodacite porphyries. The coincidence in time and space of hydrothermal alteration and intrusive activity leads to a conclusion that these are the causative intrusions.

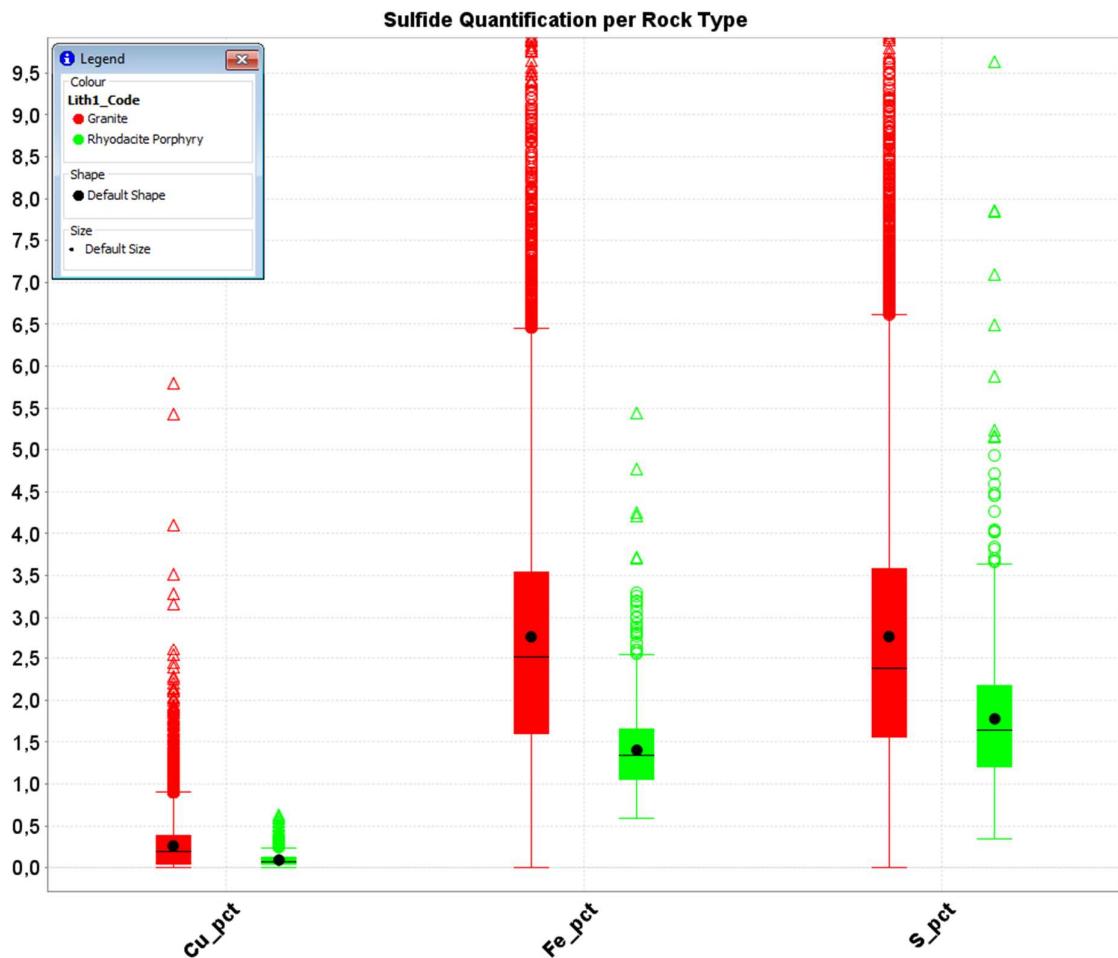

Figure 2.9: Cu, Fe and S distribution per lithology at Taca Taca Bajo. Cu and Fe sulfides were emplaced in the granite host rock preferentially over the rhyodacite porphyritic stock. High S values in the rhyodacitic porphyry are related to anhydrite appearance.

Alteration is strongly zoned outwards (Fig. 2.10a) within the granitic batholith from potassic to sericitic alteration. The sericitic alteration can be broken down into two domains: A) ore-zone phyllitic alteration, and B) pyritic halo. The ore zone phyllitic alteration is characterised by intermixed white sericite and green sericite, which prior to this study, were interpreted to be due to different ratios of white micas intermixed with fine grained chlorite. The green sericite domain is observed to have an affinity with chalcopyrite and minor bornite, hence higher copper grades (Cobeñas and Almandoz, 2015). This alteration assemblage is observed as selvages to rectilinear, thin quartz - sulfide veins and, where more intense, as coalesced selvages forming a pervasive sericitic overprint (Fig. 2.8e; Benavides, 2015). Primary sulfides have been partially overprinted by a high-sulfidation assemblage of chalcocite, bornite, pyrite and minor digenite (Fig. 2.8g). Banded quartz - molybdenite veins are observed on the outer portion of this hypogene ore zone. Outward from this zone, the pyritic halo is composed mainly of white sericite selvages (and coalesced selvages) surrounding quartz - pyrite veins with attendant phyllitic alteration (Fig. 2.8f). The spatial distribution of veins in cross section through the centre of the orebody is shown in Figure 2.11. Distally, the system transitions to a weak-moderate propylitic alteration assemblage, which is characterised by chlorite as thin veinlets and selective replacement of mafic minerals in the granite, as well as rare epidote filling fractures and replacing feldspars and mafic sites (Fig. 2.8c; Tripp, 2015a).

A 150-300 metre leached cap has developed by supergene processes after the deposit was uplifted and exhumed. This domain is depleted in copper but contains sub-economic free gold in undifferentiated limonite. The leached cap is underlain by a narrow oxide zone of inconsistent thickness, characterised by the presence of brochantite, atacamite, malachite and chrysocolla. Copper leached from the oxidised zone was re-precipitated in a supergene enrichment zone which consists mainly of chalcocite with minor digenite, together with structurally controlled supergene alunite and chalcedony (Tripp, 2015b; Waechter et al., 2015). This is the highest grade zone of the deposit. Geochronological results on supergene alunite by K/Ar suggest development of supergene mineral assemblages at 24-21 Ma (Gigola, 2008).

The ore at Taca Taca Bajo is related to an inconsistent supergene enrichment blanket and underlying hypogene mineralisation associated with the inner phyllitic alteration rather than the potassic altered domain (Fig. 2.10b). Among other factors, these complications to the

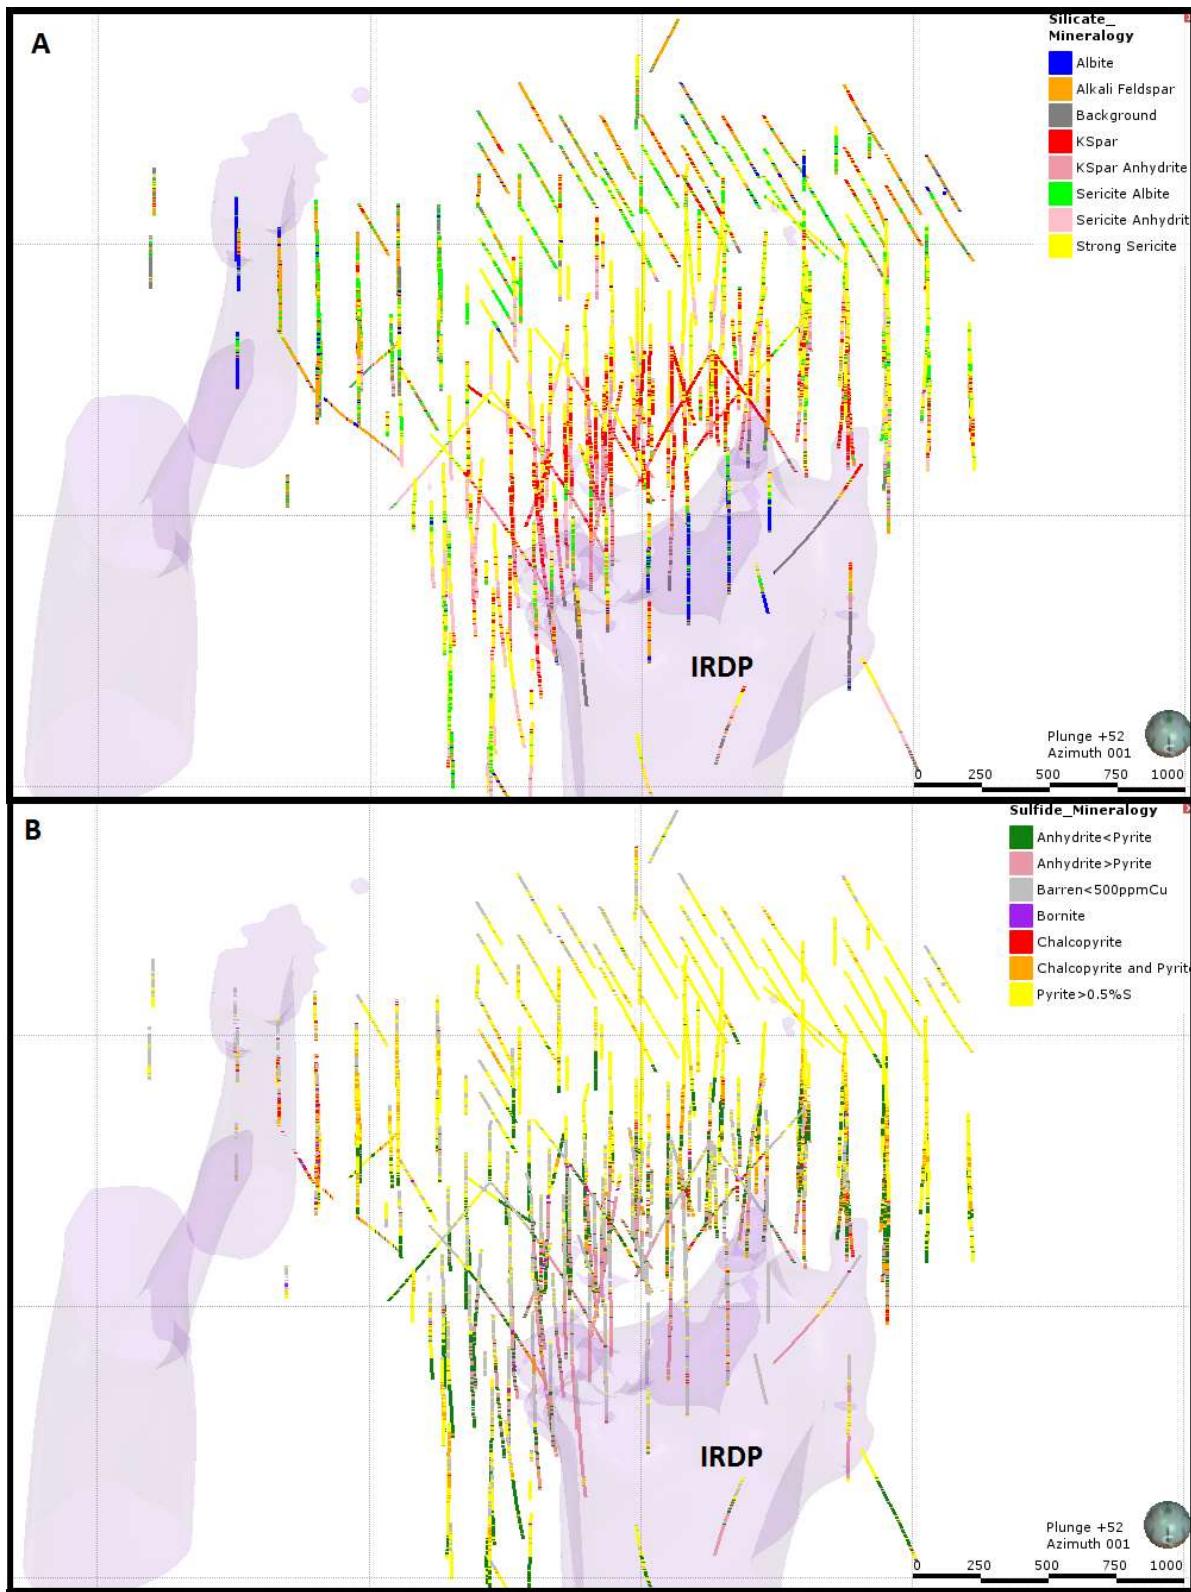

Figure 2.10: A) Alteration zonation interpreted from geochemical assays. This data has been verified and matches logged alteration (Halley, 2015). B) Hypogene mineralisation zonation interpreted from geochemical assays, also verified against paper logs (Halley, 2015). IRDP: Rhyodacite porphyry stock.

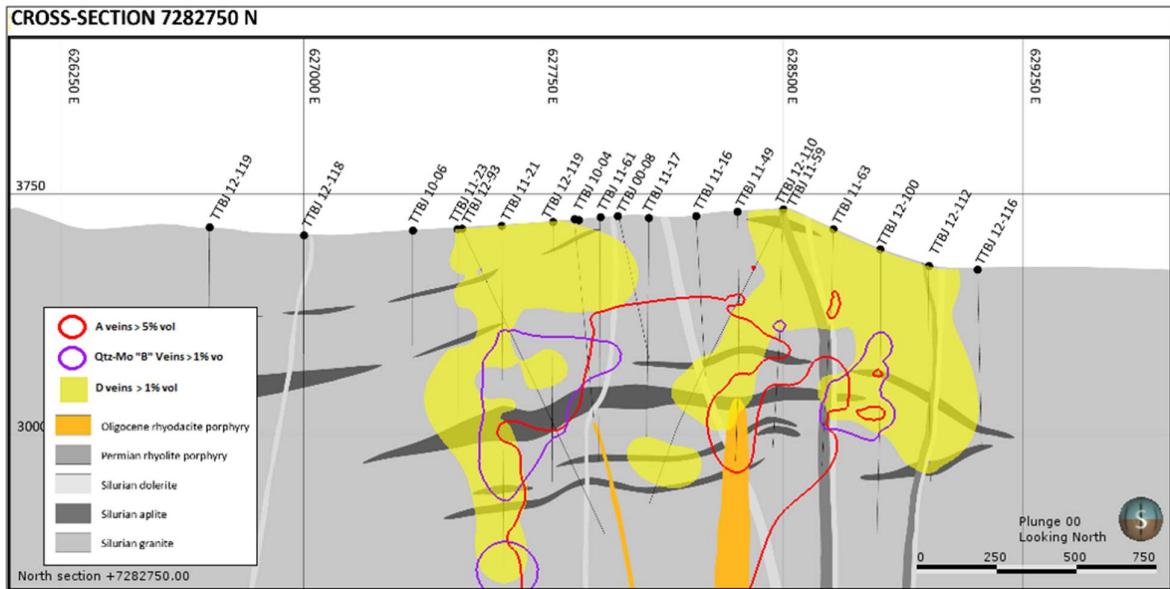

Figure 2.11: Section 7282750N through the Taca Taca Bajo orebody showing the small volume of rhyodacite porphyry and the vein distribution around it. Note that ore in Taca Taca Bajo is related to quartz-sericite-chalcopyrite "D" veins rather than the barren quartz "A" veins. From Benavides (2015).

classical porphyry model of Lowell and Guilbert (1970) led to major difficulties for early explorers at Taca Taca Bajo.

### 2.5.3 Paragenesis

Almandoz (2008) presented the current paragenetic model at Taca Taca Bajo, including all of the lithologies, alteration, veining, hypogene mineralisation and supergene mineralisation (Fig. 2.12). Rhyodacite porphyries intruded the Silurian granites and they are considered the causative intrusions for mineralisation and alteration. Potassic alteration (with very minor disseminated chalcopyrite > bornite) and barren quartz veins are the earliest events observed, followed by molybdenum deposition in banded quartz - molybdenite veins (Almandoz, 2008). This was overprinted by a green sericite alteration event which, prior to this study, was considered to be contemporary with low sulfidation state chalcopyrite - pyrite disseminated in the green sericite halos of quartz veins (Almandoz, 2008). A later high sulfidation state event brought quartz - pyrite veins with white sericite selvages, which replaced the pre-existing chalcopyrite > bornite assemblage by pyrite – bornite – chalcocite - covellite, although it had remained unclear prior to this study as to whether this latest event introduced any additional copper. Supergene enrichment and alteration products occurred roughly 6 to 8 million years later.

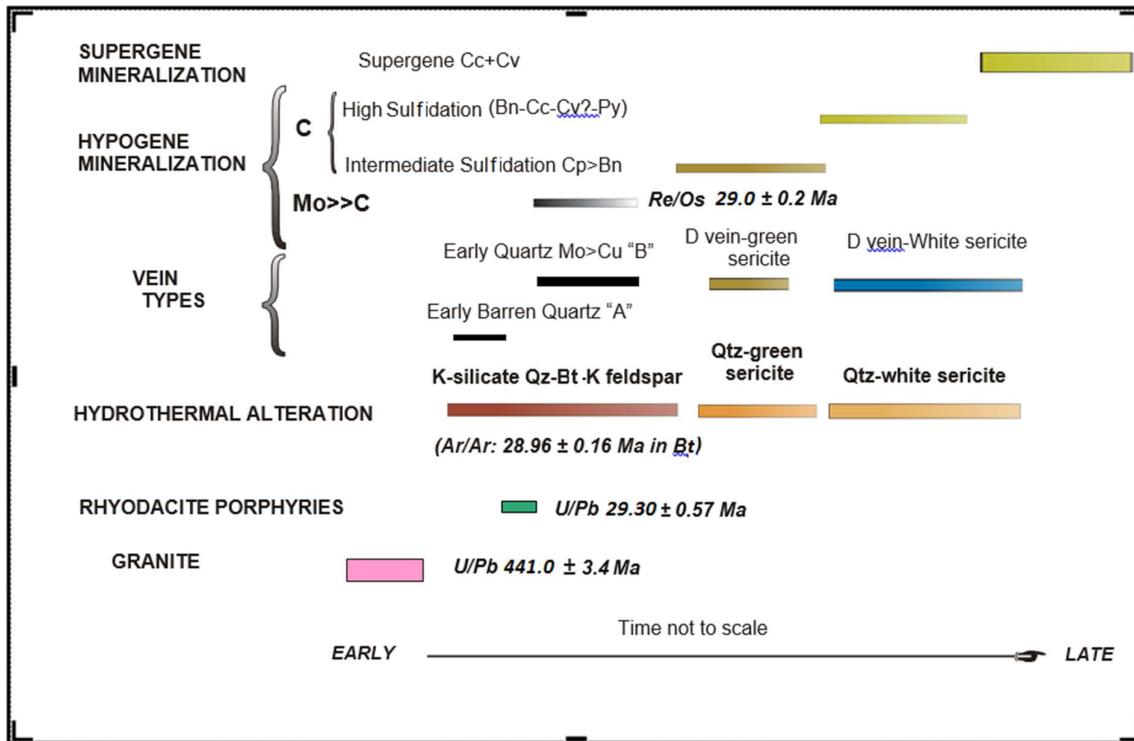

Figure 2.12: Schematic paragenetic sequence for the Taca Taca Bajo orebody. From Almandoz (2008). Cc = chalcocite, Cv = covellite, Py = pyrite, Cp = chalcopyrite, Bn = bornite, Mo = Molybdenite, Qz = quartz; Bt = biotite.

### 3. Phyllitic Alteration at Taca Taca Bajo

#### 3.1 Methodology

##### 3.1.1 Sampling

A total of 24 samples were collected from Taca Taca Bajo for this study; all of them from drill-holes (Fig 3.1). Six of the samples were collected as background control samples: three of fresh host Silurian granitic batholith, one of a potassic-altered variant of this unit, and two of potassic-altered Oligocene rhyodacite porphyry. All other samples display either white sericite, green sericite or a mixture of both, as described during logging (Table 3.1). Twenty-five laser mounts were produced from these samples (TTB\_SB14 had two mounts prepared) at the CODES lapidary (Table 3.2).

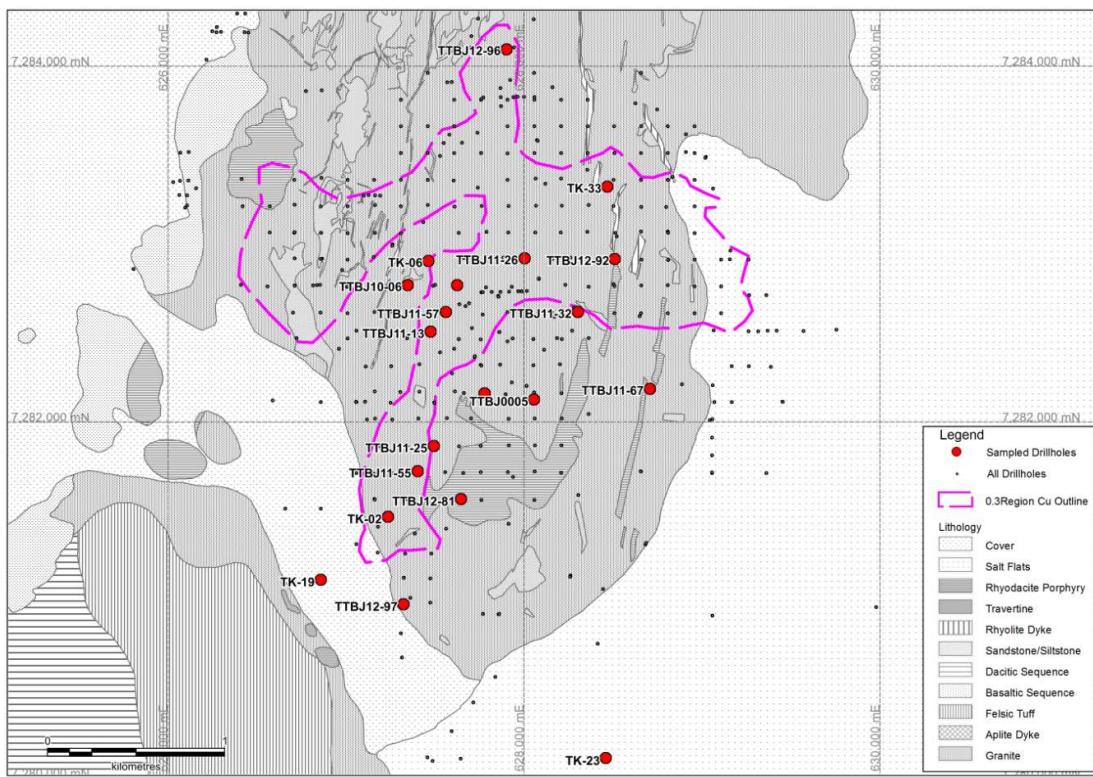

Figure 3.1: Location of drill-holes sampled in this study overlain on 0.3% Cu Indicated & Inferred Resource (Scott et al., 2013) and on surface geology (Wood et al., 2015)

### *3.1.2 Spectral Analysis*

Short wave infrared (SWIR) spectral measurements were collected from the mounts using a Terraspec 4 Mineral Spectrometer. The data were processed using The Spectral Geologist (TSG) software together with IoGas Professional to classify results by different mineralogies in relation to their spectral abundances. Sericite samples were then classified by different scalars derived from the SWIR spectra such as the wavelength of the absorption feature near 2200 nm (w2200), and parameters derived from these such as sericite crystallinity. Sericite crystallinity is calculated by dividing the depth of the hull quotient spectrum absorption feature at 2200 wavelength by that of the absorption feature near 1900 nm. The w2200 compares subtle shifts of the exact peak absorption feature at roughly 2200 wavelength, which is a strong absorption feature common to phyllosilicates (Halley, 2012). These can be used as proxies to relative temperature and pH in hydrothermal fluids.

### *3.1.3 Petrography*

Reflected light petrography of the laser mounts was conducted in order to characterise and understand the textural relationships of sulfide species. Further mineral characterisation under transmitted light was not possible due to the thickness of the laser mounts.

### *3.1.4 Scanning Electron Microprobe (SEM) and Electron Probe Microanalysis (EPMA)*

Laser mounts were carbon coated and analysed by SEM/EPMA at the Central Science Laboratory (CSL), University of Tasmania, in order to determine the different mineralogical assemblages, variations in textures, as well as classifying minerals based on their geochemical signatures. A total of 665 analyses were done with the EPMA and the data was interpreted in IoGas Professional to classify each measurement into mineral groups. 144 of those measurements were of pure sericite. SEM backscattered electron imaging was used to define textural variations of sericite and relict alteration textures. With this information, the LA-ICPMS laser points were planned for trace level geochemistry of sericite, apatite, monazite and xenotime sites.

### *3.1.5 Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICPMS)*

A total of 318 laser spots on sericite sites were analysed with a 20-micron beam. The primary standard was a NIST612 sample and secondary standards were BCR-2 and GSD-1G, all of which were analysed between samples. Each measurement was reviewed for quality standards and clipped or discarded where impurities had been ablated. The data was normalised using an initial assumption of 21% Al for sericite, then converted to total oxide concentrations using the GSD method. A loss on ignition (LOI) of 4.0% was assumed for sericite, and where required, total oxide concentrations were corrected to add to 96%. All values were then converted back to parts per million.

Apatite, monazite and xenotime sites were also ablated for geochemical analysis and U-Pb dating using a 13-micron laser beam and NIST-610 as a primary standard. This was done to attempt to resolve the possibility for overprinting hydrothermal systems complicating the sericite signatures. The ablation process was comparable to that used for the sericite ablation, with the addition of  $^{204}\text{Pb}$ ,  $^{206}\text{Pb}$ ,  $^{207}\text{Pb}$  and  $^{208}\text{Pb}$  to the geochemical measurements. Apatite sites were normalised to 39.36% Ca, monazite to 67.94% Ce and xenotime to 38% Y. For monazite and xenotime measurements, a  $^{140}\text{Ce}$  internal standard was used and the data were then corrected so the total sum of rare earth elements (RRE) balanced against the phosphate ( $\text{PO}_4$ ) component. They were then corrected for the 53% REE molar representation in stoichiometric monazite and xenotime. Technical issues that occurred when analysing the apatite samples prevented proper use of the geochemical or geochronological data, as the spot size on apatite samples was set smaller than the spot size on reference samples. These analyses are hence not reported. Concordia diagrams were generated by Mr. Jay Thompson from UTAS Earth Sciences department to plot the apatite, monazite and xenotime Pb and U isotopic ratios in order to calculate ages and errors.

Only 13 chlorite sites and 7 epidote sites were observed under SEM. They were marked and analysed in the LA-ICPMS with a 20-micron laser beam, using a NIST-612 samples as primary standard between mounts. During early stage data validation, the data were discarded as the fine grained nature of the minerals did not allow for quantification of the chemistry of these minerals.

### *3.1.6 Potassium Feldspar Staining*

Following mount preparation, the offcut core samples were stained with sodium cobaltinitrite to demonstrate the distribution and abundance of potassium feldspar alteration in the samples. The objective of this is to discriminate phyllitic alteration overprinting potassian alteration from that affecting common orthoclase-bearing granite. This procedure was done with the help of Dr. Lejun Zhang from the ARC TMVC Research Hub.

### *3.1.7 Quartz Cathodoluminescence (CL)*

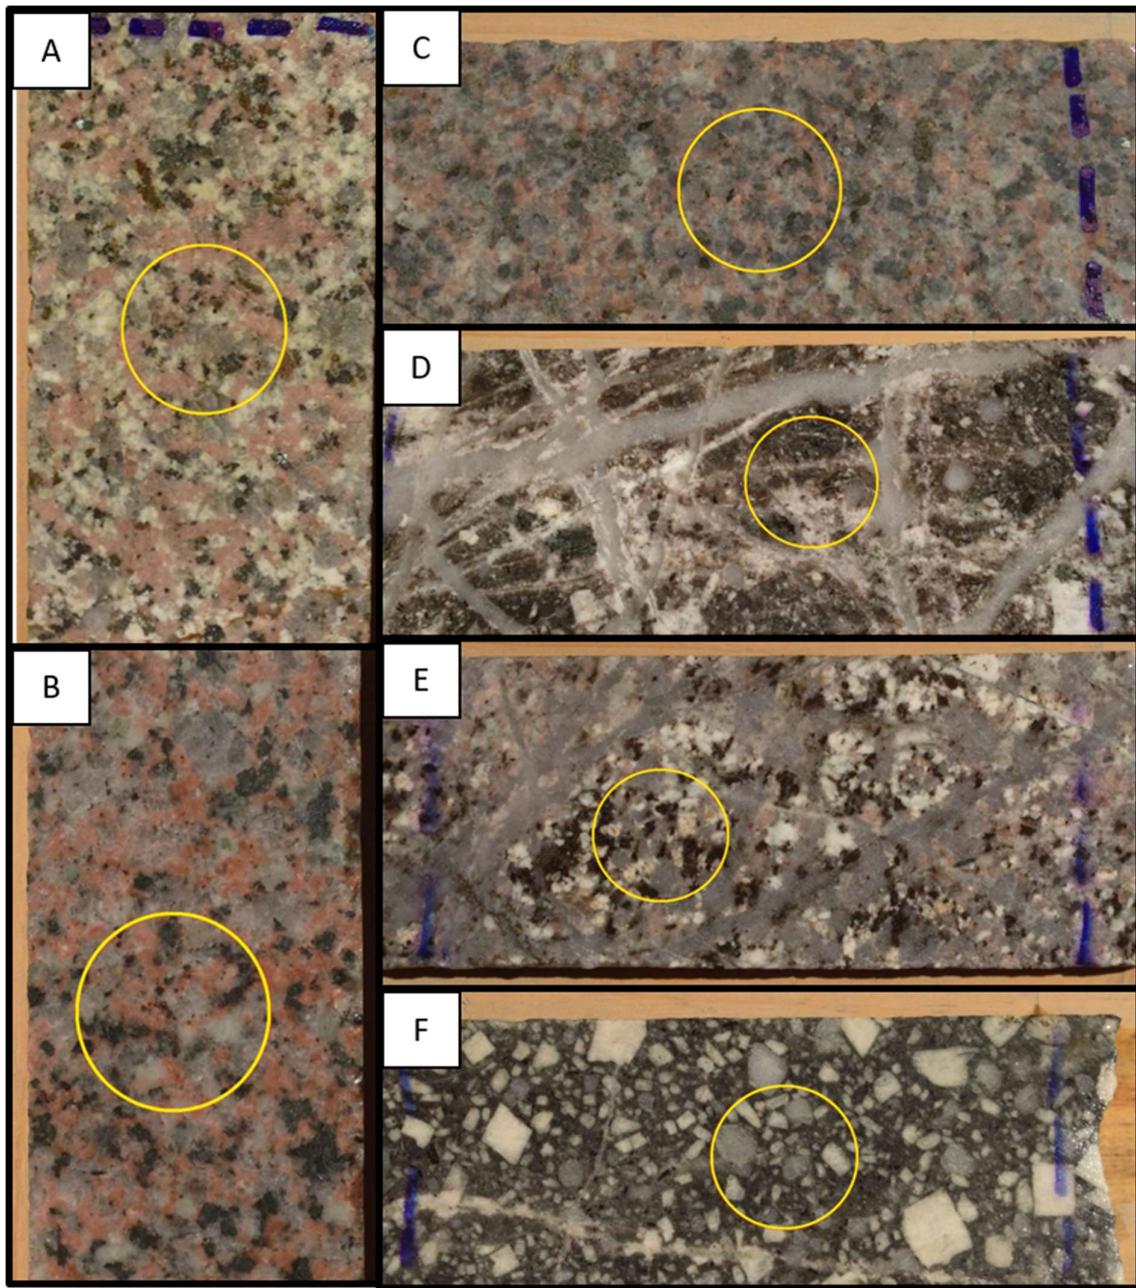

CL imaging of quartz was done on 14 samples where hydrothermal quartz was observed to be intimately related to sericite alteration. The imagery was collected using a Cameca cathodoluminescence detector attached to an FEI Quanta 600 environmental scanning electron microprobe (SEM) at the CSL. Polished mounts were examined using the instrument at an accelerating voltage of 15 kV and beam current of ~3 nA. This procedure was carried out by Dr. Lejun Zhang from the ARC TMVC Research Hub. The aim was to highlight internal textures in quartz to observe differences which might permit differentiation of different stages of phyllitic alteration and/or reversal relationships in the temperature gradient, which would suggest overprinting of another system.

## 3.2 Sample Descriptions

### *3.2.1 Background Samples*

TTB\_SB01: Medium to coarse-grained, equigranular granite from the Silurian batholith. Plagioclase is slightly altered to clays while biotite and hornblende are slightly altered to chlorite. Major components: 5-10% mafics (biotite and hornblende), 30% plagioclase, 30% orthoclase, 30% quartz (Fig. 3.2a).

TTB\_SB02: Medium to coarse-grained, equigranular granite from the Silurian batholith. Plagioclase is slightly altered to clays (greenish) while biotite and hornblende are fresh. There is red staining of orthoclase. Major components: 5-10% mafics (biotite and hornblende), 30% plagioclase, 30% orthoclase, 30% quartz (Fig. 3.2b).

*Figure 3.2: Background samples. Yellow circle is 1-inch laser mount location. Descriptions in section 3.2.1. A) TTB\_SB01; B) TTB\_SB02; C) TTB\_SB03; D) TTB\_SB04; E) TTB\_SB05; F) TTB\_SB06*

TTB\_SB03: Medium-grained, equigranular granite from the Silurian batholith. Biotite and hornblende are slightly weathered to clays, while quartz, orthoclase and plagioclase are fresh. Major components: 10% mafics (biotite and hornblende), 30% plagioclase, 30% orthoclase, 30% quartz (Fig. 3.c).

TTB\_SB04: Coarse-grained porphyritic rhyodacite porphyry with strong pervasive secondary biotite altering the groundmass (roughly 50%). Medium to coarse plagioclase and quartz

phenocrysts (20%) are observed. Very erratic chalcopyrite is disseminated in the groundmass. It is cut by a barren quartz vein stockwork (0.5 centimetres thick on average, 30% of rock) and very minor quartz-pyrite-sericite vein stringers in adjacent core, though not in sample, cross cut all previously described veining (Fig. 3.2d).

TTB\_SB05: Medium-grained, equigranular potassic altered granite from the Silurian batholith host, cut by barren quartz veins (0.4 cm thick on average, 30%). Secondary biotite alteration (roughly 15%) is replacing mafic sites. Weak quartz-pyrite veins with sericite selvages and sulfide stringers are reopening barren quartz veins. The mount was sampled away from these late stage veins (Fig. 3.2e).

TTB\_SB06: Coarse-grained, crowded rhyodacite porphyry. Plagioclase and quartz phenocrysts (40%) are within a groundmass completely replaced by secondary, shreddy biotite. Very minor barren quartz veins present in this sample (Fig. 3.2f).

### *3.2.2 Green Sericite Samples*

TTB\_SB08: Equigranular granite with pervasive green sericite alteration. Relict potassic alteration displays secondary biotite replacing mafics. Relict quartz from granite host is observed. Sulfides are dominated by chalcopyrite with very minor pyrite replacements. This sample is adjacent to a 5-10-centimetre-wide rhyodacite porphyry dyke (Fig. 3.3a).

TTB\_SB09: Equigranular granite with pervasive green sericite alteration. Patches of relict potassic alteration on granite display secondary biotite replacing mafic sites. Quartz-chalcopyrite-green sericite veins crosscut early barren quartz veins (Fig. 3.3b).

TTB\_SB17: Pervasive green sericite alteration in equigranular granite. Patches of green sericite and chalcopyrite appear to be replacing mafic sites. Minor white sericite and pyrite is observed replacing chalcopyrite (Fig. 3.3c).

TTB\_SB19: Strong pervasive green sericite alteration in equigranular granite host. Veins and disseminations of bornite-pyrite are replacing chalcopyrite. Relict quartz from granite host is observed (Fig. 3.3d).

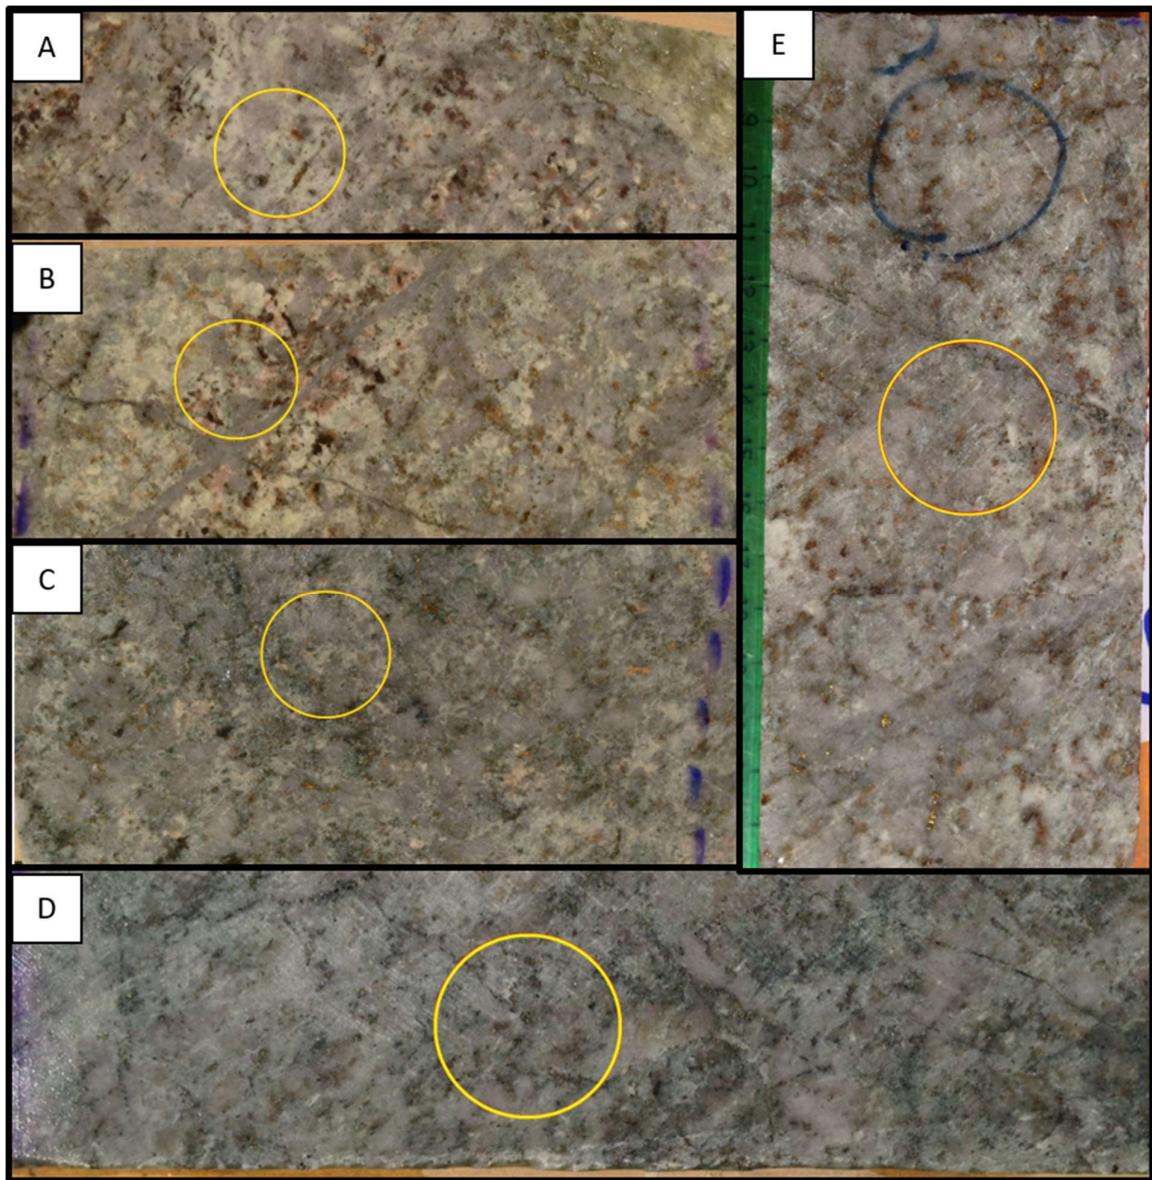

Figure 3.3: Green sericite samples. Yellow circle is 1-inch laser mount location. Descriptions in section 3.2.2 A) TTB\_SB08; B) TTB\_SB09; C) TTB\_SB17; D) TTB\_SB19; E) TTB\_SB24

TTB\_SB24: Equigranular granite with pervasive green sericite alteration as patches around relict secondary biotite sites. Chalcopyrite is disseminated within green sericite patches and in quartz-chalcopyrite veins display weak high sulfidation replacement by pyrite-bornite (Fig. 3.3e).

### 3.2.3 Mixed Sericite Samples

TTB\_SB07: Granite sample with pervasive green sericite and white sericite alteration. Chalcopyrite is disseminated within green sericite patches replacing relict biotite sites and

appears to be overprinted by bornite-pyrite. Replacement fronts on sulfides suggest that the high sulfidation overprint is related to white sericite alteration as a later event (Fig. 3.4a).

TTB\_SB10: Orthoclase-biotite altered granite cut by quartz – chalcopyrite – pyrite - bornite veins with white and green sericite selvages, which have re-opened barren quartz veins. Different sericite types appear to be coexisting in vein selvages (Fig. 3.4b).

TTB\_SB14: Porphyritic rhyodacite with strong secondary biotite replacement of groundmass, cut by two distinct vein types: quartz – pyrite >> chalcopyrite veins with green sericite selvage and quartz veins with white sericite selvages. Two mounts were created from this sample, TTB\_SB14a from a green sericite selvage and TTB\_SB14b from a white sericite selvage (Fig. 3.4c).

TTB\_SB16: Pervasive green and white sericite alteration on potassic altered rhyodacite porphyry (as observed on adjacent rocks). A relict coarse-grained, crowded porphyritic texture is almost completely replaced and pyrite is observed in veins and patches. The mount was made on the white sericite domain (Fig. 3.4d).

TTB\_SB20: Pervasive white and green sericite alteration on granite. Relict quartz crystals and barren quartz veins cut by quartz, pyrite ± bornite veins with white sericite ± green sericite selvages. Green sericite is also observed as patches with disseminated sulfides (Fig. 3.4e).

TTB\_SB21: Potassic altered granite with secondary biotite and orthoclase cut by quartz-chalcopyrite>>pyrite veins with green sericite selvages. Minor white sericite overprint and everything is cross-cut by late gypsum veins. The mount was located on the transition zone between potassic altered granite and vein selvage (Fig. 3.4f).

TTB\_SB22: Pervasive green > white sericite overprint of potassic altered granite. Sericite occurs as coalesced selvages to quartz, pyrite ± bornite veins that reopened and cross cut barren quartz veins (Fig. 3.4g).

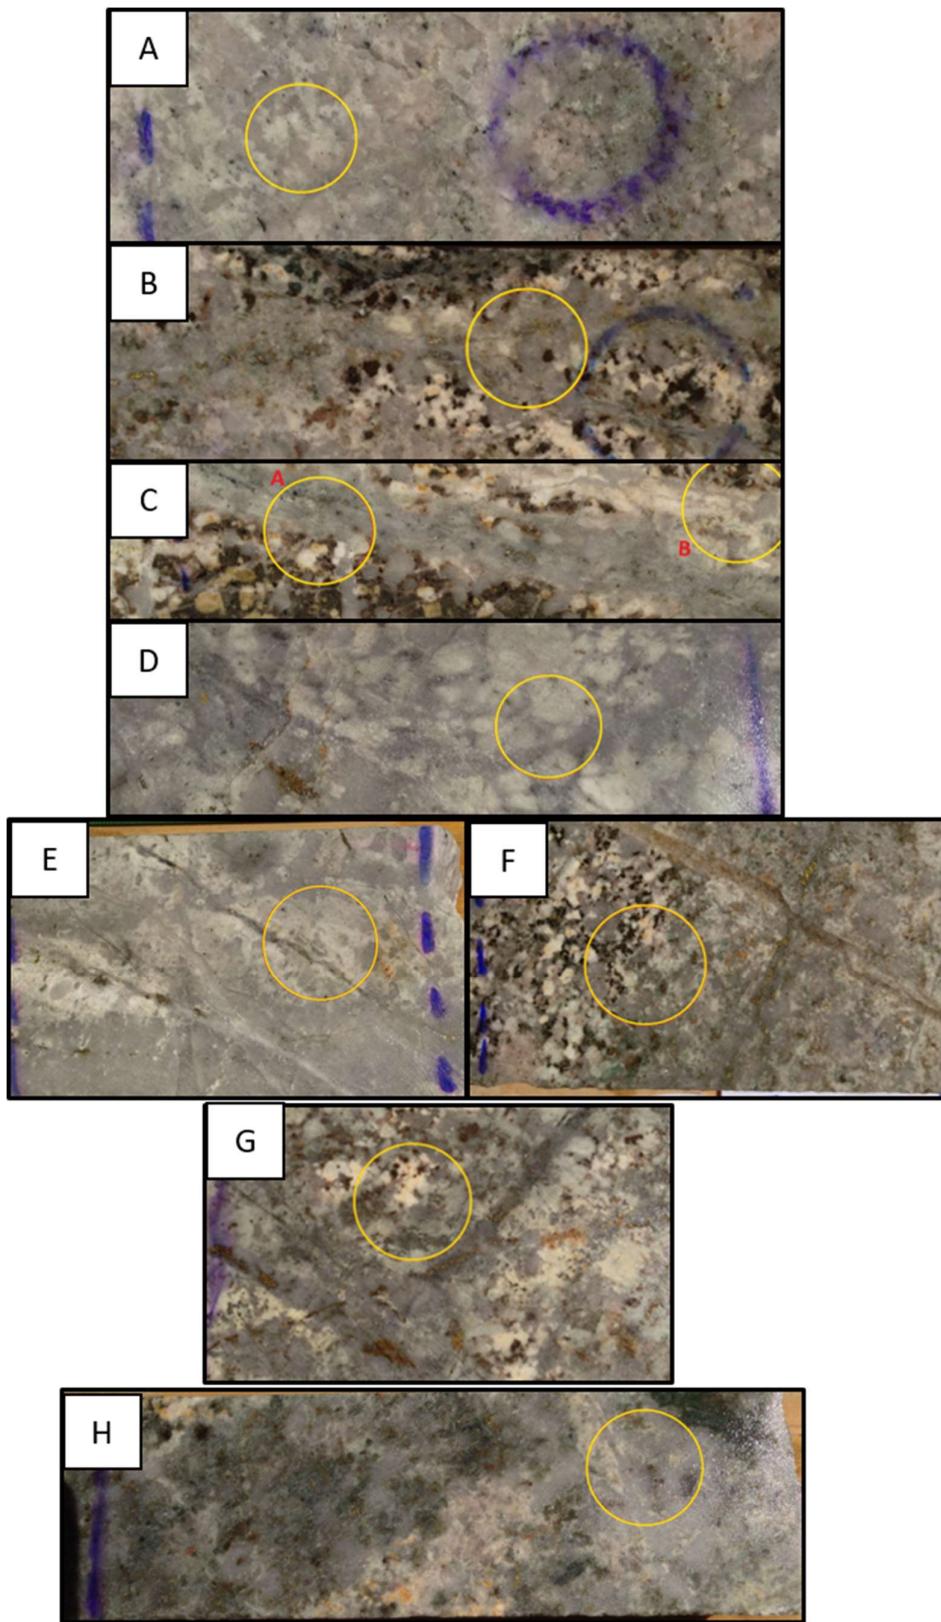

Figure 3.4: Mixed green and white sericite Samples. Yellow circle is 1-inch laser mount location. Descriptions in section 3.2.3.  
A) TTB\_SB07; B) TTB\_SB10; C) TTB\_SB14 with both mounts; D) TTB\_SB16; E) TTB\_SB20; F) TTB\_SB21; G) TTB\_SB22; H)  
TTB\_SB23

TTB\_SB23: Granite with relict potassic alteration overprinted by strong patches of green sericite and disseminated chalcopyrite, pyrite and minor bornite. Later overprint of white sericite is observed as selvage to quartz ± sulfide veins. Minor anhydrite observed. The mount was located on the contact of white sericite selvage with green sericite patches (Fig. 3.4h).

### 3.2.4 White Sericite Samples

TTB\_SB11: Equigranular granite with relict potassic alteration and barren quartz veins, overprinted by white sericite alteration as selvages to quartz, pyrite veins. White sericite selvages coalesce to form roughly 10 centimetres of pervasive white sericite alteration with only relict quartz crystals. The mount was taken within this pervasive alteration (Fig. 3.5a).

TTB\_SB12: Equigranular granite with pervasive white sericite alteration as coalesced selvages to quartz-pyrite veins. Roughly 10% pyrite content is observed in veins and selvages (Fig. 3.5b).

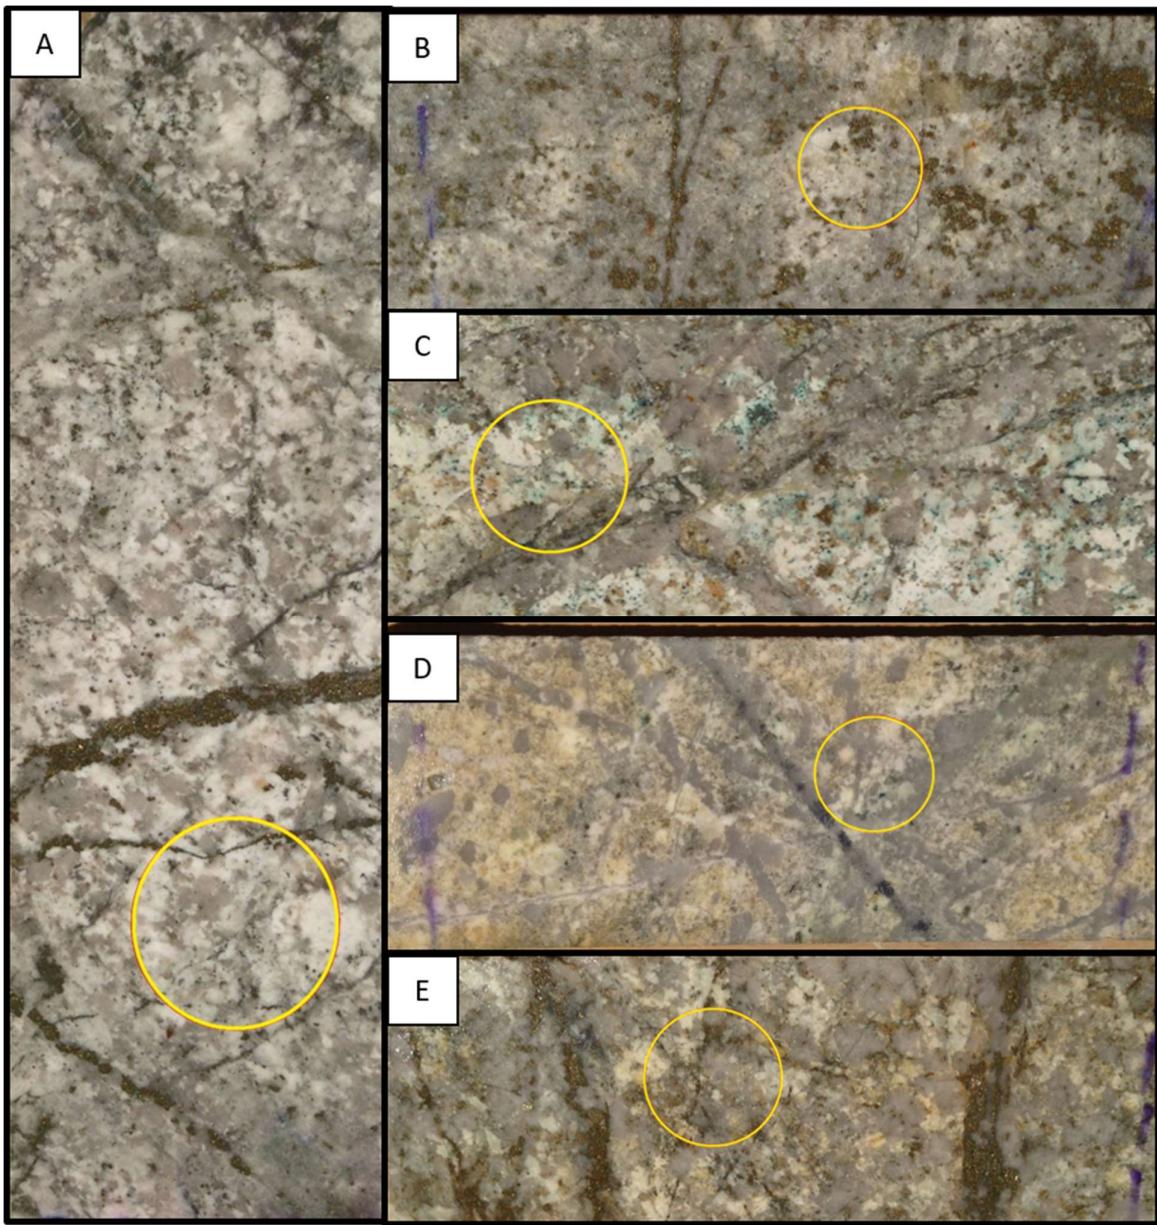

TTB\_SB13: Equigranular granite with pervasive white sericite alteration (minor green sericite) Quartz-bornite-pyrite veins crosscut relict quartz crystals. The greenish tint is from copper oxides after bornite (Fig. 3.5c).

TTB\_SB15: Potassic altered rhyodacite porphyry with barren quartz veins, cut by a quartz-molybdenite vein. Overprinted by minor fine, discontinuous pyrite-bornite>>chalcopyrite stringers and pervasive white sericite (Fig. 3.5d).

TTB\_SB18: Equigranular granite with relict potassic alteration cut by quartz – pyrite >> chalcopyrite vein stockwork and pervasive white sericite alteration. Pyrite is observed in veins (5%; Fig. 3.5e).

## 3.3 Sulfide Characterisation

Petrographic investigation of each mount was used to refine the sulfide mineralogy observed in logging, and to reveal significant textural information. Background samples tend to lack sulfides, but samples TTB\_SB04 and TTB\_SB05 from the potassic altered rhyodacite porphyry display minor disseminated chalcopyrite that is partly replaced by pyrite and by pyrite-bornite-chalcocite, respectively.

*Figure 3.5: White sericite samples. Yellow circle is 1-inch laser mount location. Descriptions in section 3.2.4 A) TTB\_SB11; B) TTB\_SB12; C) TTB\_SB13; D) TTB\_SB15; E) TTB\_SB18*

With a few exceptions (e.g., TTB\_SB14a, which was adjacent to a white sericite vein), the samples that had been logged as pure\* green sericite (\*in the sense that all the sericite was green, rather than any mixture of green and white; Table 3.1) contain a sulfide assemblage comprising either pure chalcopyrite (Fig. 3.6a) or chalcopyrite partly replaced by pyrite, bornite, chalcocite  $\pm$  digenite as a high-sulfidation overprint (Fig. 3.6b). In samples logged as having a pure white sericite phyllitic alteration facies, pyrite is the dominant sulfide species although in some cases relict chalcopyrite was observed (Fig. 3.6c). These samples are

interpreted as either replacement of chalcopyrite by pyrite or belong to the outer pyritic halo where no primary chalcopyrite has been observed.

The samples logged with proportions of both green and white sericite types show replacement of chalcopyrite by pyrite broadly proportional to the ratio of white to green sericite. This can be observed texturally in almost all samples (Fig. 3.6d through 3.6f).

Three main associations can be distinguished between the logged sericite components and observed sulfides:

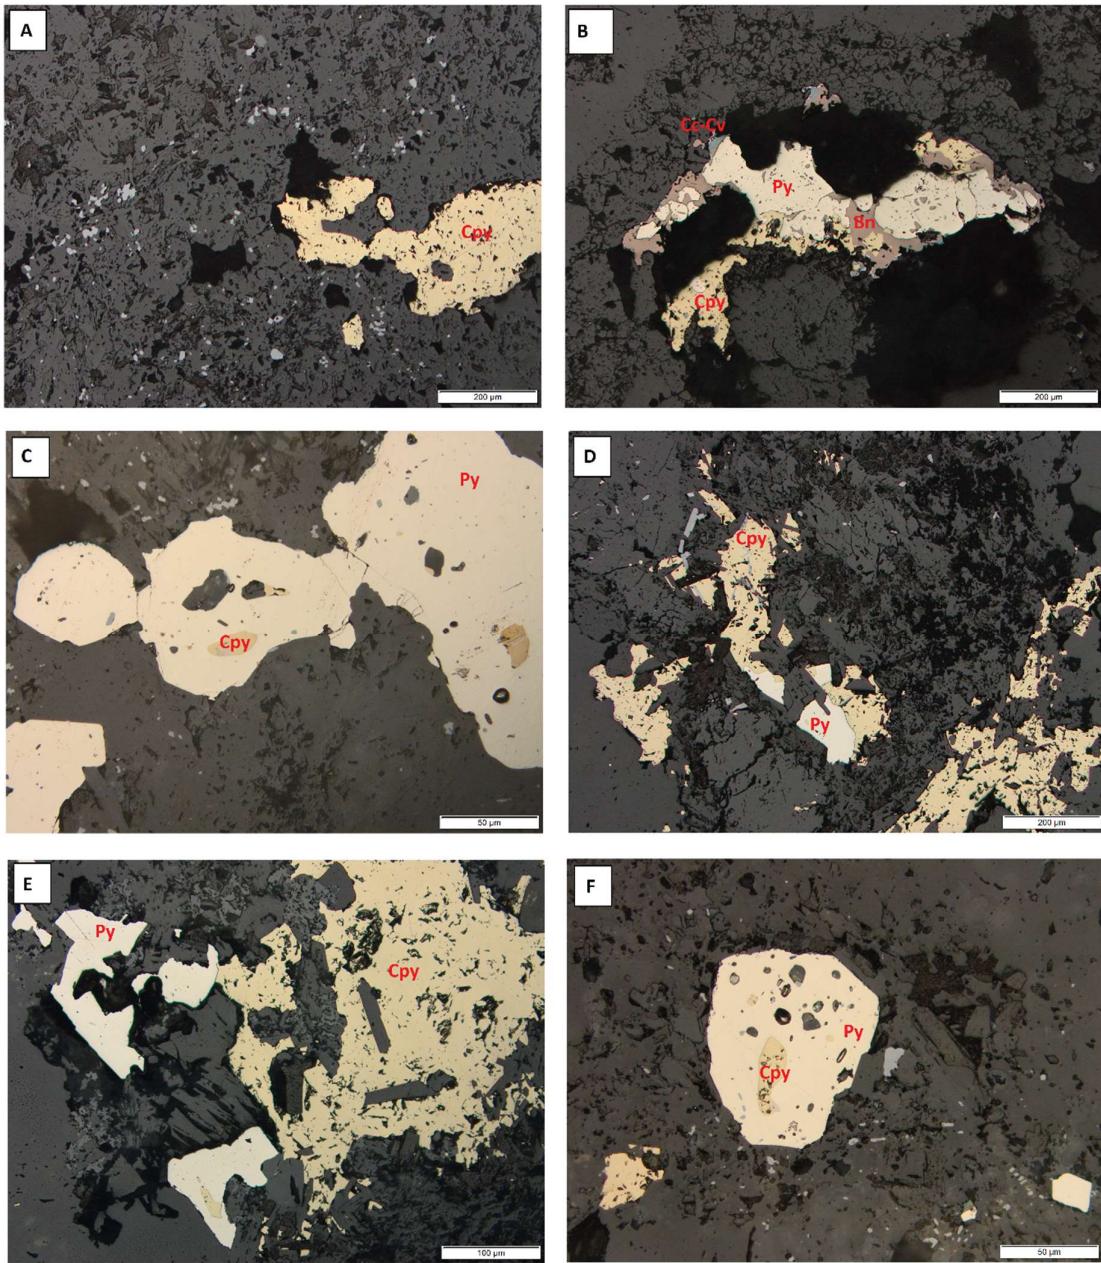

1. There is a strong correlation between green sericite occurrence and chalcopyrite.
2. White sericite is always present in some degree in those samples in which pyrite has replaced chalcopyrite. White sericite is always present in samples in which pyrite is the only sulfide.
3. White sericite has a strong correlation with the presence of high sulfidation sulfide assemblage.

No paragenetic evidence has been observed that distinguishes the pyrite-only and the high sulfidation sulfide assemblages, as pyrite is stable under both conditions.

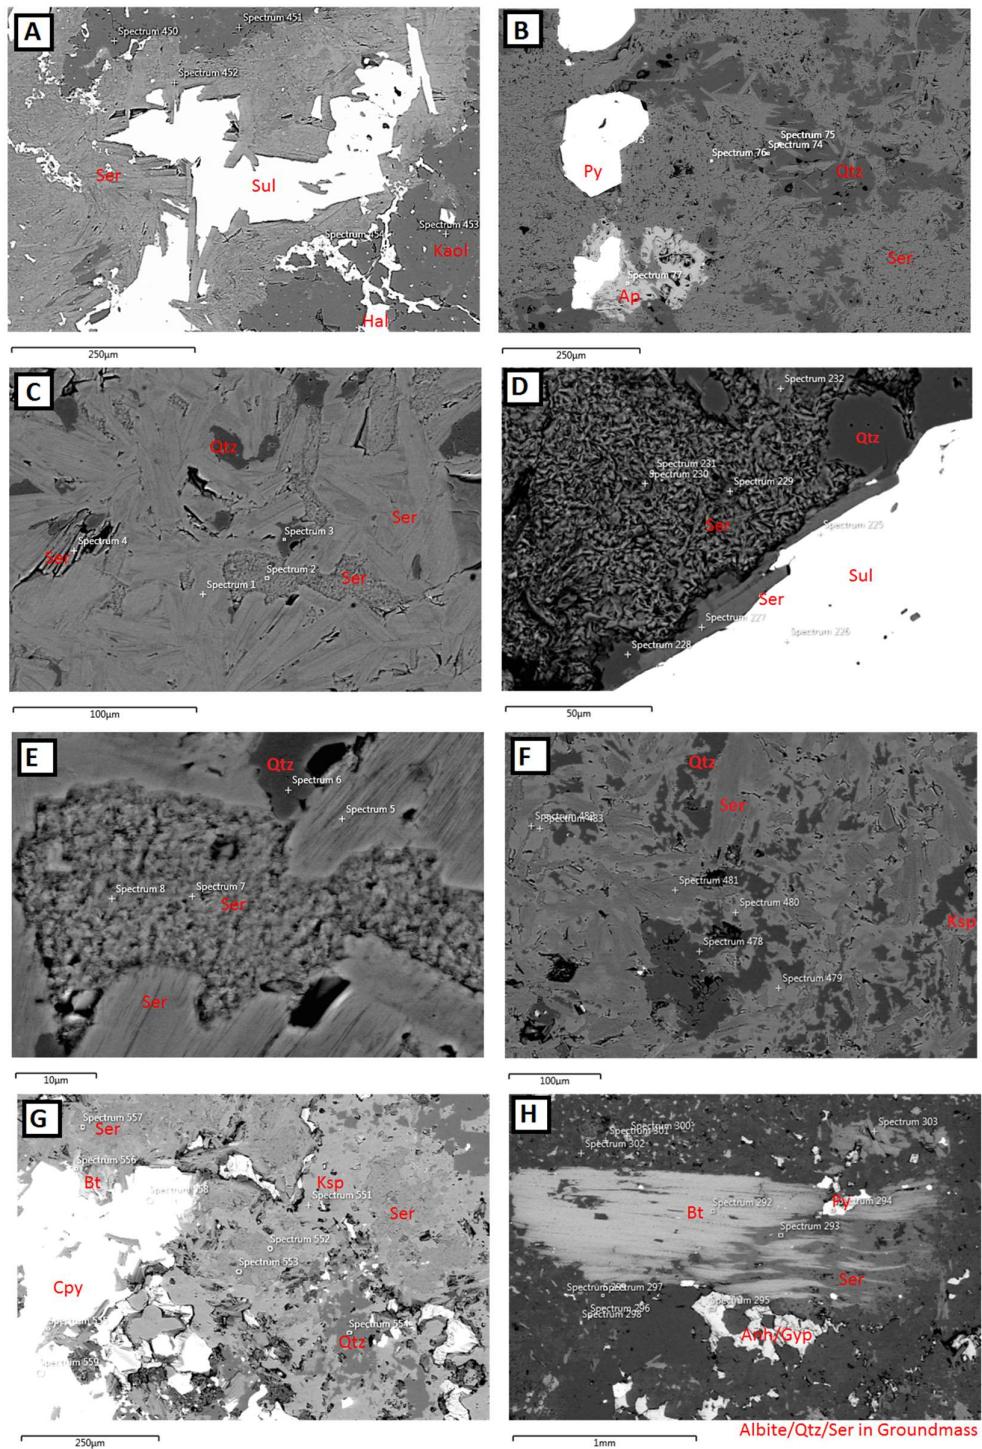

## 3.4 Sericite Characterisation

### *3.4.1 Textural Characterisation*

Examination of sericite textures under SEM revealed that there are two different morphological populations of sericite-group minerals. The dominant sericite morphology in most samples takes the form of coarse (50-100 µm) euhedral blades (Fig. 3.7a-b) and it can be observed in samples with logged white sericite, green sericite or mixtures of both types. Fine grained (1-2µm), shreddy sericite (Fig. 3.7c-d-e) is also observed in several samples from each sericite colour group, although it appears preferentially in green sericite or mixed samples. The shreddy sericite morphology is uncommon in white sericite samples.

**Figure 3.6:** Transmitted light microscope images from laser mounts showing sulfide textural relationships. A) TTB\_SB08. Disseminated chalcopyrite together in pervasive green sericite sample. B) TTB\_SB15. High sulfidation replacement of chalcopyrite on sample with white sericite overprint of potassic rhyodacite porphyry. C) TTB\_SB18. Relict chalcopyrite cores in potassic altered granite with pervasive white sericite-pyrite overprint. D) TTB\_SB23. Weak pyrite replacement of chalcopyrite at the contacts of a white sericite vein selvage and green sericite + potassic altered granite. E) TTB\_SB17. Moderate replacement of chalcopyrite by pyrite on predominant green sericite sample with minor white sericite. F) TTB\_SB21. Strong pyrite replacement of chalcopyrite, leaving only a chalcopyrite core. Mixed sericite overprint in potassic altered granite. Legend: Py: Pyrite, Cpy: Chalcopyrite, Bn: Bornite, Cc: Chalcocite, Cv: Covellite.

**Figure 3.7: SEM textural variation in sericite.** A) TTB\_SB23. Coarse, bladed sericite in vein selvage to sulfide-bearing micro veinlet. B) TTB\_SB12. Pervasive coarse, bladed sericite with relict quartz from granite. C) TTB\_SB07. Pervasive coarse, bladed sericite with relict patches of quartz and fine grained shreddy sericite. D) TTBJ\_SB11. Fine grained shreddy sericite and quartz cut by quartz-sulfide-coarse, bladed sericite vein. Shreddy sericite appears to be within relict mafic site of granite E) TTB\_SB07. Close-up of sericite contacts from (C) shows that pervasive coarse grained sericite is leaving patches of pre-existing fine, shreddy sericite and quartz. F) TTB\_SB21. Moderate pervasive coarse, bladed sericite overgrowing potassic alteration with orthoclase flooding. G) TTB\_SB17 Moderate, patchy sericite overprint on orthoclase-biotite altered granite with chalcopyrite. H) TTB\_SB14b. Sericite replacing biotite phenocryst in white sericite overprint of rhyodacite porphyry.

Fine-grained, shreddy sericite has a patchy appearance. It resembles the morphology of classical secondary biotite alteration in porphyry systems (e.g., Titley and Beane, 1981) and here seems to have nucleated in the ferromagnesian sites of the potassically-altered protolith (Fig. 3.7g). The euhedral bladed sericite has a more pervasive nature and is interpreted to destroy pre-existing textures, including the fine grained, shreddy sericite (Fig. 3.7e). In samples where phyllitic alteration is less intense, coarse sericite blades are correspondingly less pervasive, revealing the pre-existing alteration assemblages. In sample TTB\_SB21, that relict texture is intense pervasive orthoclase alteration, among which only patches of quartz remain from the granite protolith (Fig. 3.7f-g).

In TTB\_SB14b, where a white sericite vein cuts the biotite rich rhyodacite porphyry, the partial replacement of a euhedral, primary biotite grain by sericite can be observed (Fig. 3.7h). To judge by the amount of secondary biotite alteration in the background samples, an attractive explanation for the shreddy sericite is that it represents a texture-preserving replacement of shreddy, secondary biotite alteration, potentially after a step through shreddy chlorite, which is commonly observed in western Pacific porphyry systems (Cooke et al., 1998).

### *3.4.2 Analytical Characterisation*

Electron microprobe data (Appendix 1) from analysed sericite sites show that the coarse, bladed sericite has muscovite compositions, whereas the fine grained, shreddy sericite is elevated in Fe and Mg (and K), and plots on a trend between sericite and biotite in a chlorite – muscovite – K-feldspar – biotite general element ratio (CMKB) diagram (e.g., Fig. 3.8). The  $(\text{Fe}+\text{Mg})/\text{Al}$  values in the trend suggest a relatively more phengitic composition of the shreddy sericite. These data are not definitive due to analytical limitations of this technique, but the trends suggest compositional distinction between the two populations.

Laser spots were planned to ablate fine, shreddy sericite agglomerations and coarse, bladed sericite, respectively, and were selected to target the purest end member morphology types available. However, due to the resolution limitations of the LA-ICPMS microscope, there is a degree of uncertainty how much of each type was ablated where both coexist. Because of this, the data are presented in Appendix 2 honouring the proportions of green and white sericite components as originally logged.

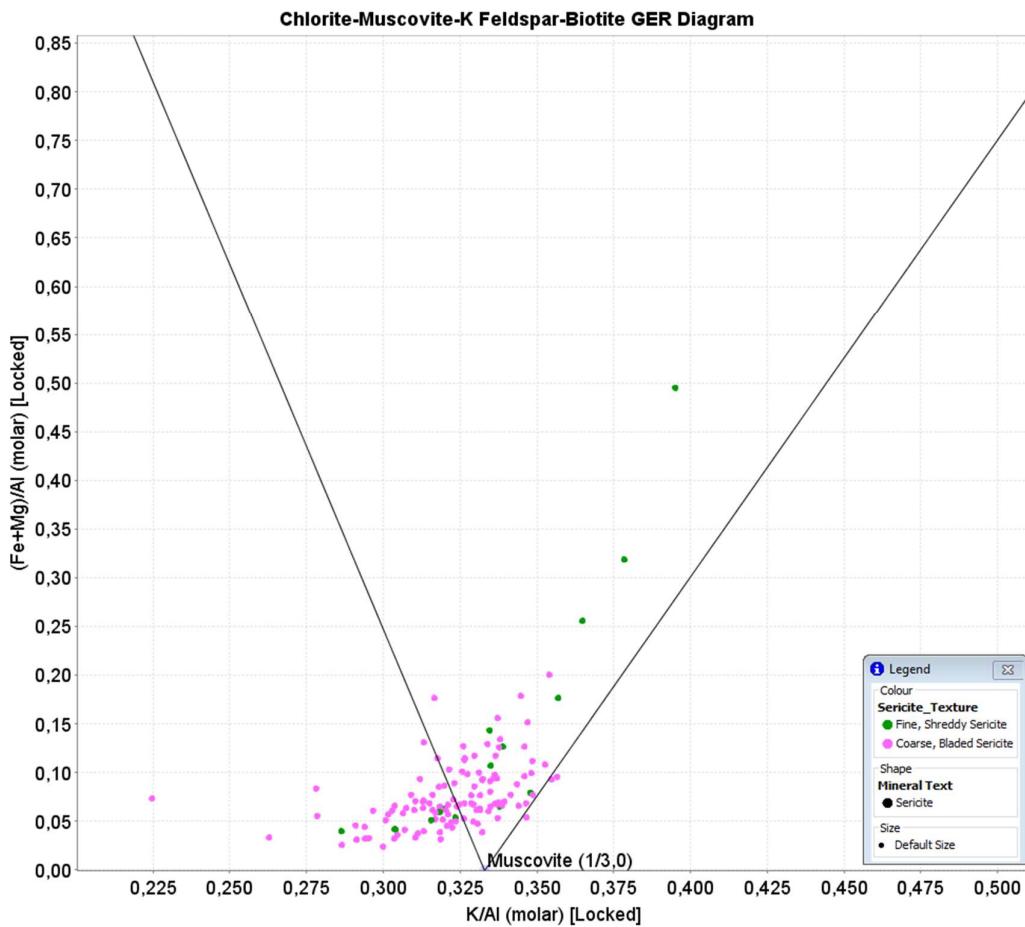

Figure 3.8: Chlorite-muscovite-K feldspar-biotite GER (CMKB) diagram showing the different geochemical trends for the variations in sericite texture. Analytical data from EPMA.

After data validation, reduction and corrections, the measurements from samples with pure white sericite plot in the same region of the CMKB diagram as the coarse grained, bladed sericite as analysed by SEM (Fig. 3.9). The samples logged with mixed colour sericite or pure green sericite plot on two different trends, one identical to the fine grained shreddy sericite observed in the EPMA and another minor trend with elevated K, trending towards orthoclase. Together these data suggest that the logged white sericite is muscovite (Figs. 3.8 and 3.9), which occurs pervasively in the rocks as coarse grained blades overprinting all pre-existing textures. The logged green sericite is therefore considered to be phengite that occurs as a fine grained, shreddy replacement of pre-existing mineral sites, most commonly secondary and primary biotite, and locally also orthoclase.

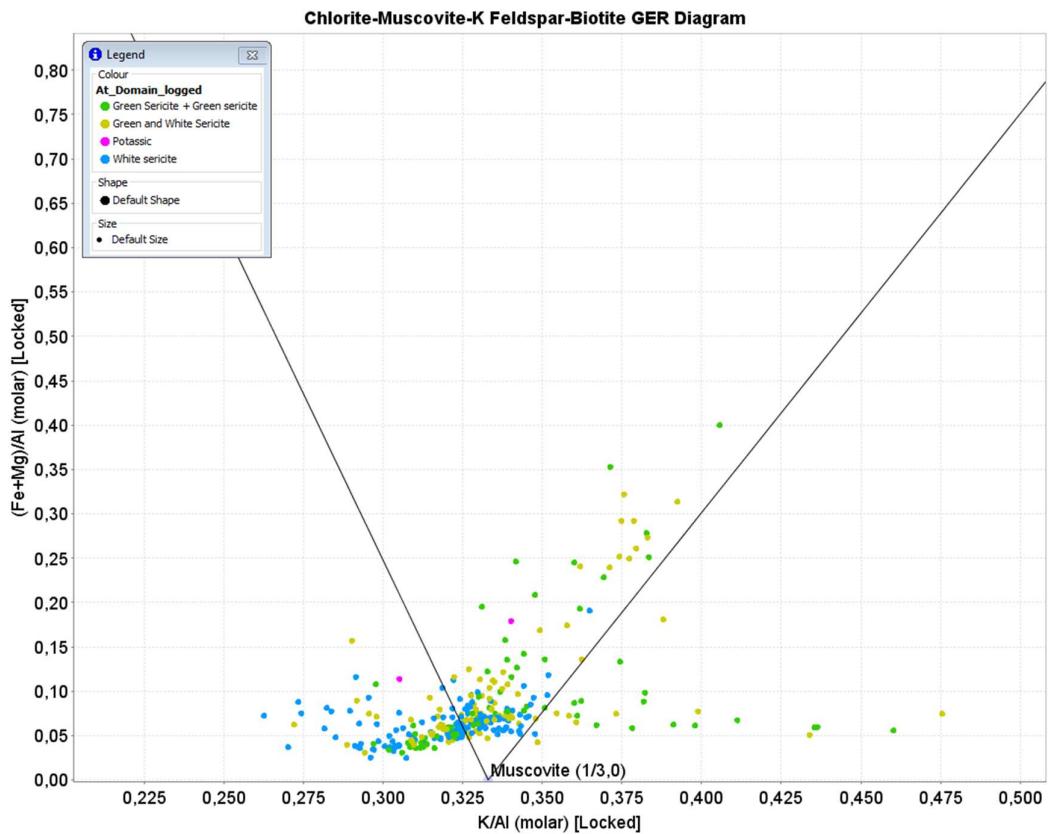

Figure 3.9: Chlorite-muscovite-K feldspar-biotite GER (CMKB) diagram showing the LA-ICPMS geochemistry of sericite sites from samples with logged white, green or mixed sericite.

The interpretation of phengite is confirmed by the SWIR spectral data (Fig. 3.10). There is a clear trend from shorter wavelengths of the w2200 scalar at the muscovitic composition, to longer wavelengths among phengitic compositions. This suggests that the muscovite formed at lower pH conditions than the phengite, and that the phengite probably formed by replacement of other silicates, at higher temperature and pH (e.g. Cohen, 2011; Halley, 2012). The sericite crystallinity scalar is calculated by dividing the hull quotient spectrum depth at w2200 by that at hqd1900, but no consistent relationship was observed between crystallinity, and composition, colour or morphology. In contrast, the backscattered electron imagery permits unambiguous recognition of the crystallinity differences between the muscovite and phengite at Taca Taca Bajo (Fig. 3.7).

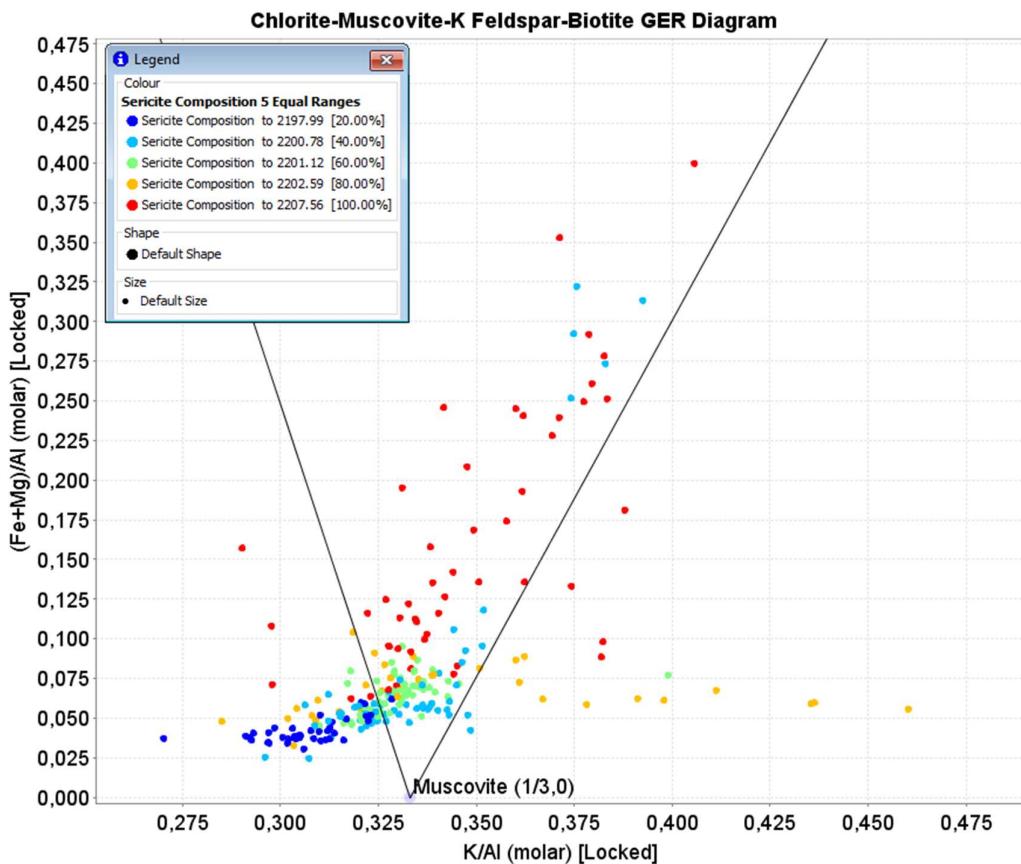

Figure 3.10: Chlorite-muscovite-K feldspar-biotite GER (CMKB) diagram coloured by the w2200 scalar on sericite samples. The population extending onto the biotite trend tend to have a longer wavelength 2200 absorption feature.

This study of sericite permits some discussion of the paragenesis of copper mineralisation at Taca Taca Bajo. To resolve this, it is necessary to address the high sulfidation state sulfide and alteration assemblage. Since some samples show partial replacement of chalcopyrite by pyrite, bornite, chalcocite  $\pm$  digenite, it was not possible to understand whether a sample containing only the high sulfidation assemblage formed by direct precipitation of these minerals, or by replacement of chalcopyrite, or replacement of other sulfides. Hence, to understand the relationship between copper grade and the muscovite and phengite alteration facies, it was necessary to consider only those samples without a high sulfidation overprint. Figure 3.11 shows the CMKB diagram coloured by the Cu grade in the two-meter interval from which the individual samples were selected. These assays are assumed to be representative of the smaller samples investigated here by micro-analytical techniques. The assays were conducted by ALS Chemex and provided to this study by FQM. The relationship

between sericite type and sulfides observed from hand specimens, where Cu sulfides were related to the green sericite, is also observed from the WR assays. Samples that have phengitic sericite show elevated Cu grades, whereas the samples with muscovitic sericite tends to be below 0.1% Cu. This, together with the petrographic observations (section 3.2) suggests that the phengite is either intimately associated with the deposition of chalcopyrite or did not corrode or destroy pre-existing chalcopyrite. In contrast, muscovite is associated with pyrite after replacement of chalcopyrite.

Trace element compositions of sericite were analysed from the granite-protolith samples only, as under-sampling of mineralised porphyritic rhyodacite was unavoidable due to the nature of this porphyry deposit (Fig. 2.9). As with the copper grades, the samples with high sulfidation state sulfide assemblages must be treated separately to understand their chemical input. Samples with alteration logged as green sericite or mixed sericite (which contain some phengite) are enriched in Li, Zn, Mn and Ni, whereas they exhibit bimodal behaviour with V, Ba and to a lesser degree Sn, and Sr (Fig. 3.12). The consistent enrichments could be due to hydrothermal input (i.e. related to phengite precipitation), whereas the bimodality of the other elements notable in this alteration facies could be related to partial geochemical conservation of the original trace element composition of biotite or orthoclase during replacement by phengite. Similar patterns are observed when the data are treated in terms of the observed sulfide assemblage. Samples that contain chalcopyrite have a gross correlation to the phengite samples (Figs. 3.12 and 3.13) in their trace element geochemistry, i.e., these are the same samples that have elevated Li, Zn, Mn and Ni. An imperfect negative correlation exists between phengite abundance and with the Cu and Pb content of sericite (Fig. 3.13).

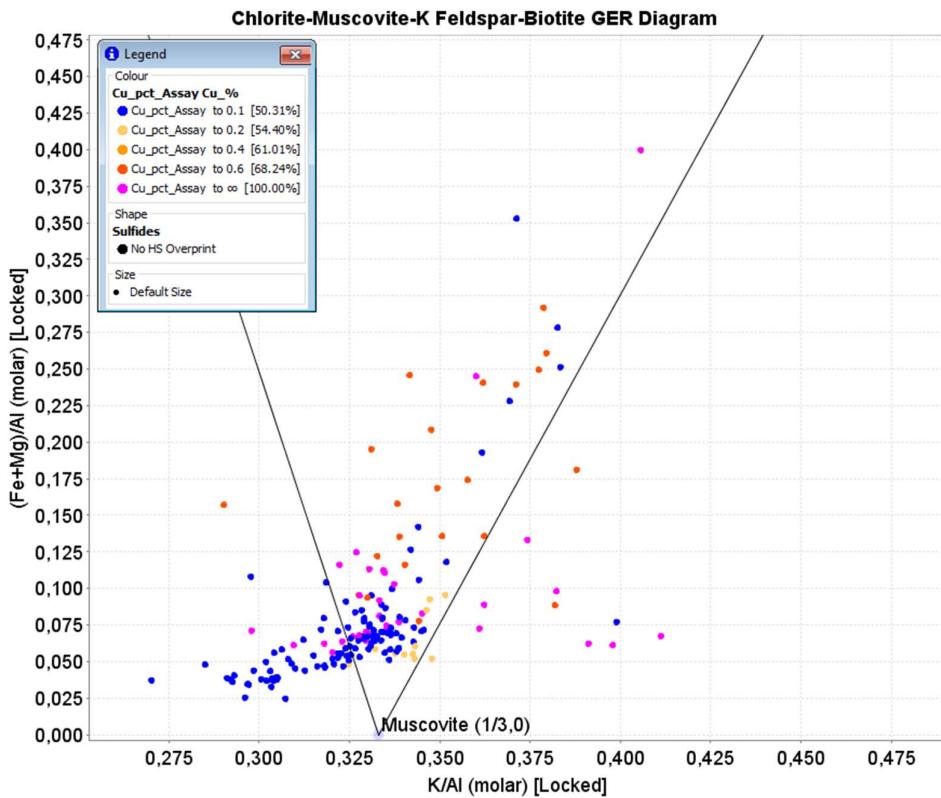

Figure 3.11: Chlorite-muscovite-K feldspar-biotite GER (CMKB) diagram of sericite analysis coloured by the whole rock Cu (%) assay of the 2-meter interval where it belongs.

### 3.4.3 High sulfidation overprint

A similar analysis was conducted including samples in which the high sulfidation assemblage is present. Samples in which there is a higher degree of replacement of primary sulfides by the high sulfidation assemblage, are dominated by sericite with compositions closer to muscovite. This phenomenon is observed in the Ba, Li and Ni trends (Fig. 3.14) and a comparable macroscopic relationship between white sericite and the high sulfidation sulfide assemblage has long been observed by the exploration geologists at Taca Taca Bajo. These observations are consistent with the interpretation of a fundamental relationship between the muscovite phase of phyllitic alteration and high sulfidation state replacement of chalcopyrite. These are interpreted to be part of the same event, as discussed in section 3.3.

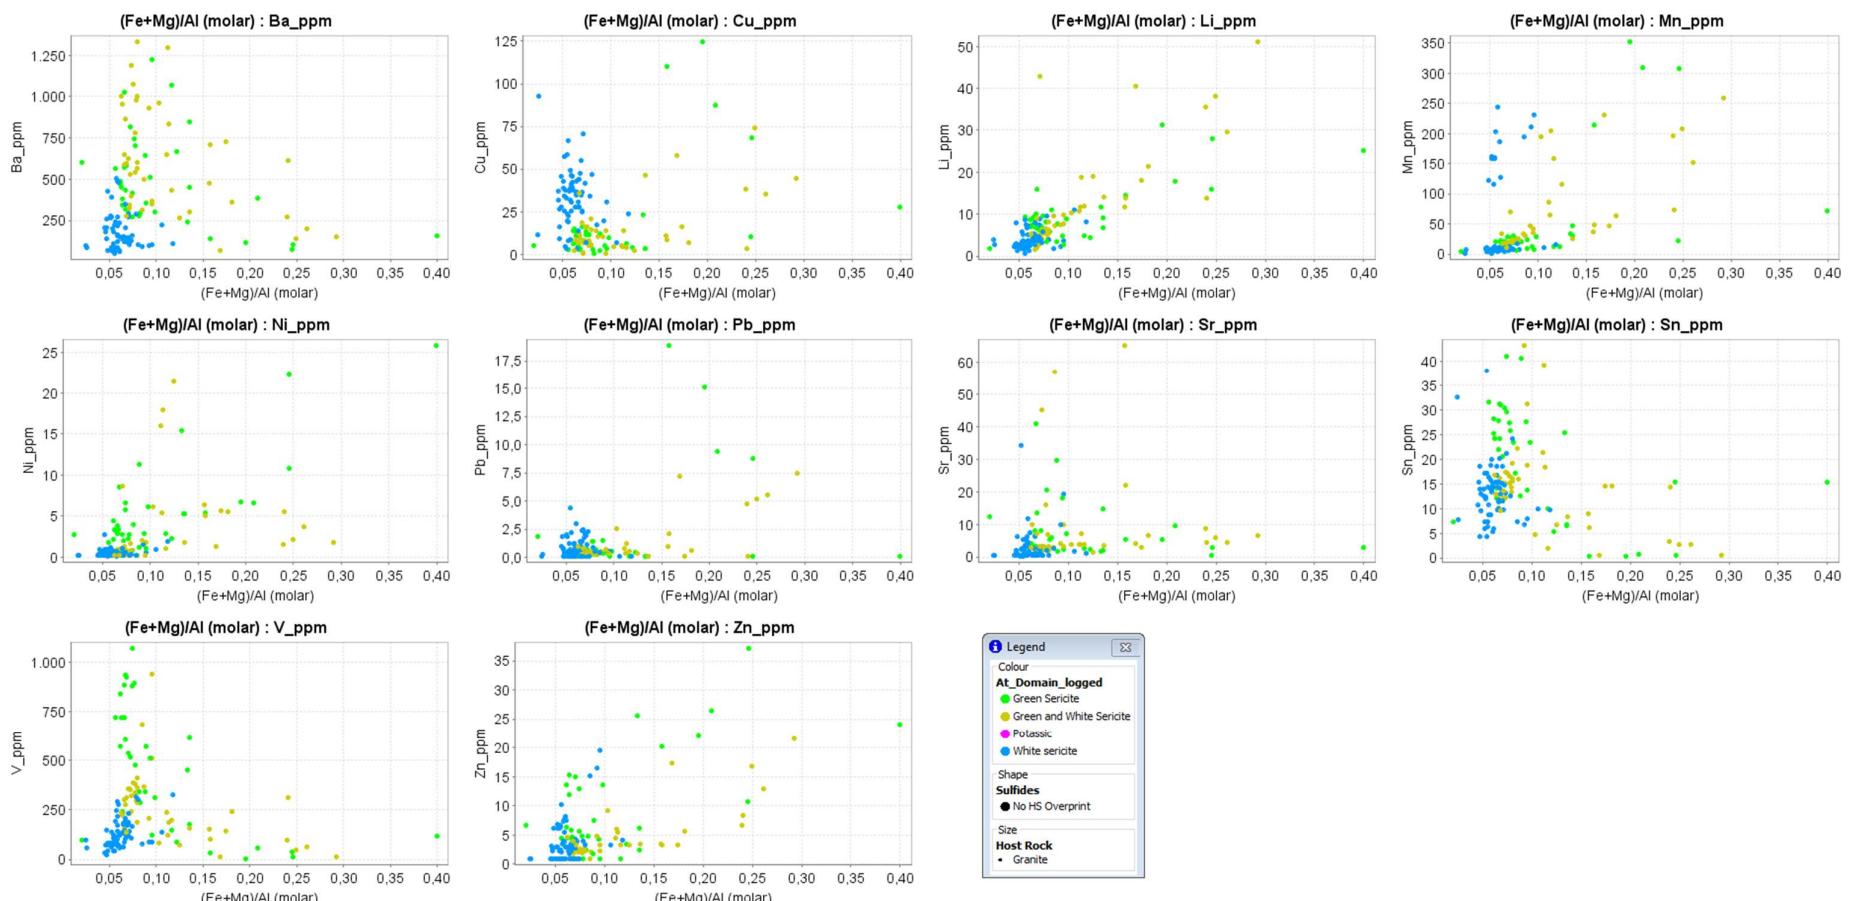

Figure 3.12: Trace element geochemistry of analysed sericite samples, coloured by the sericite type logged. Data has been filtered to show only samples in granite and without high sulfidation overprint.

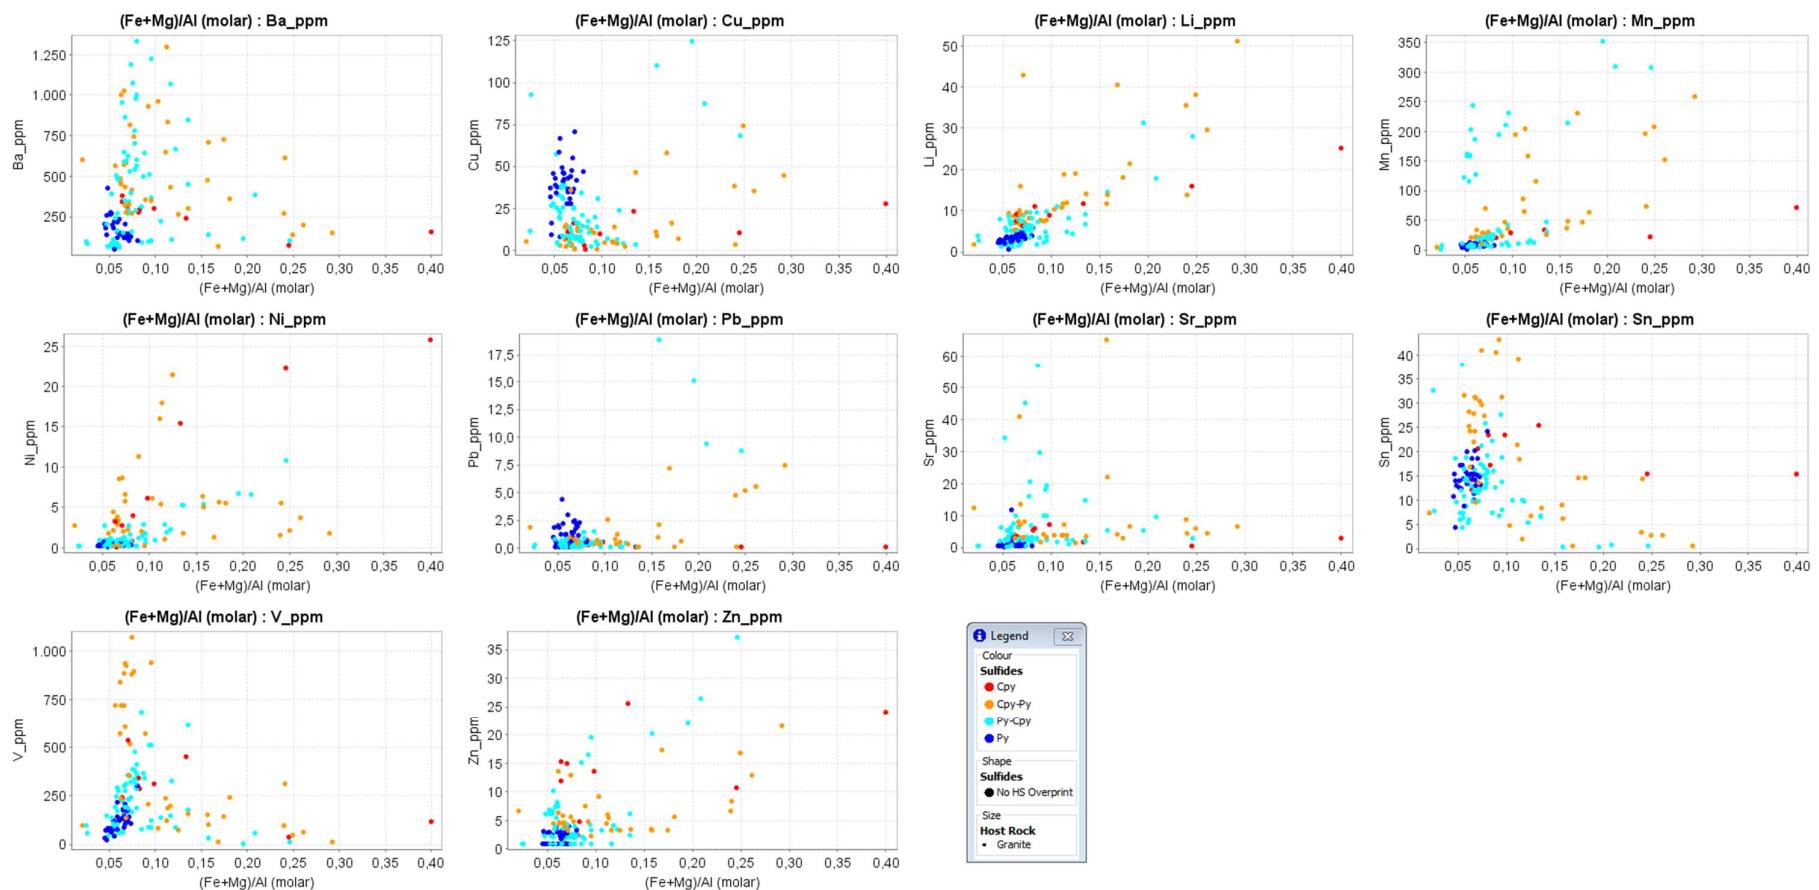

Figure 3.13: Trace element geochemistry of analysed sericite samples, coloured by the sulfide assemblage recognised on the mount. Data has been filtered to show only samples in granite and without high sulfidation overprint. All data located in Appendix 2.

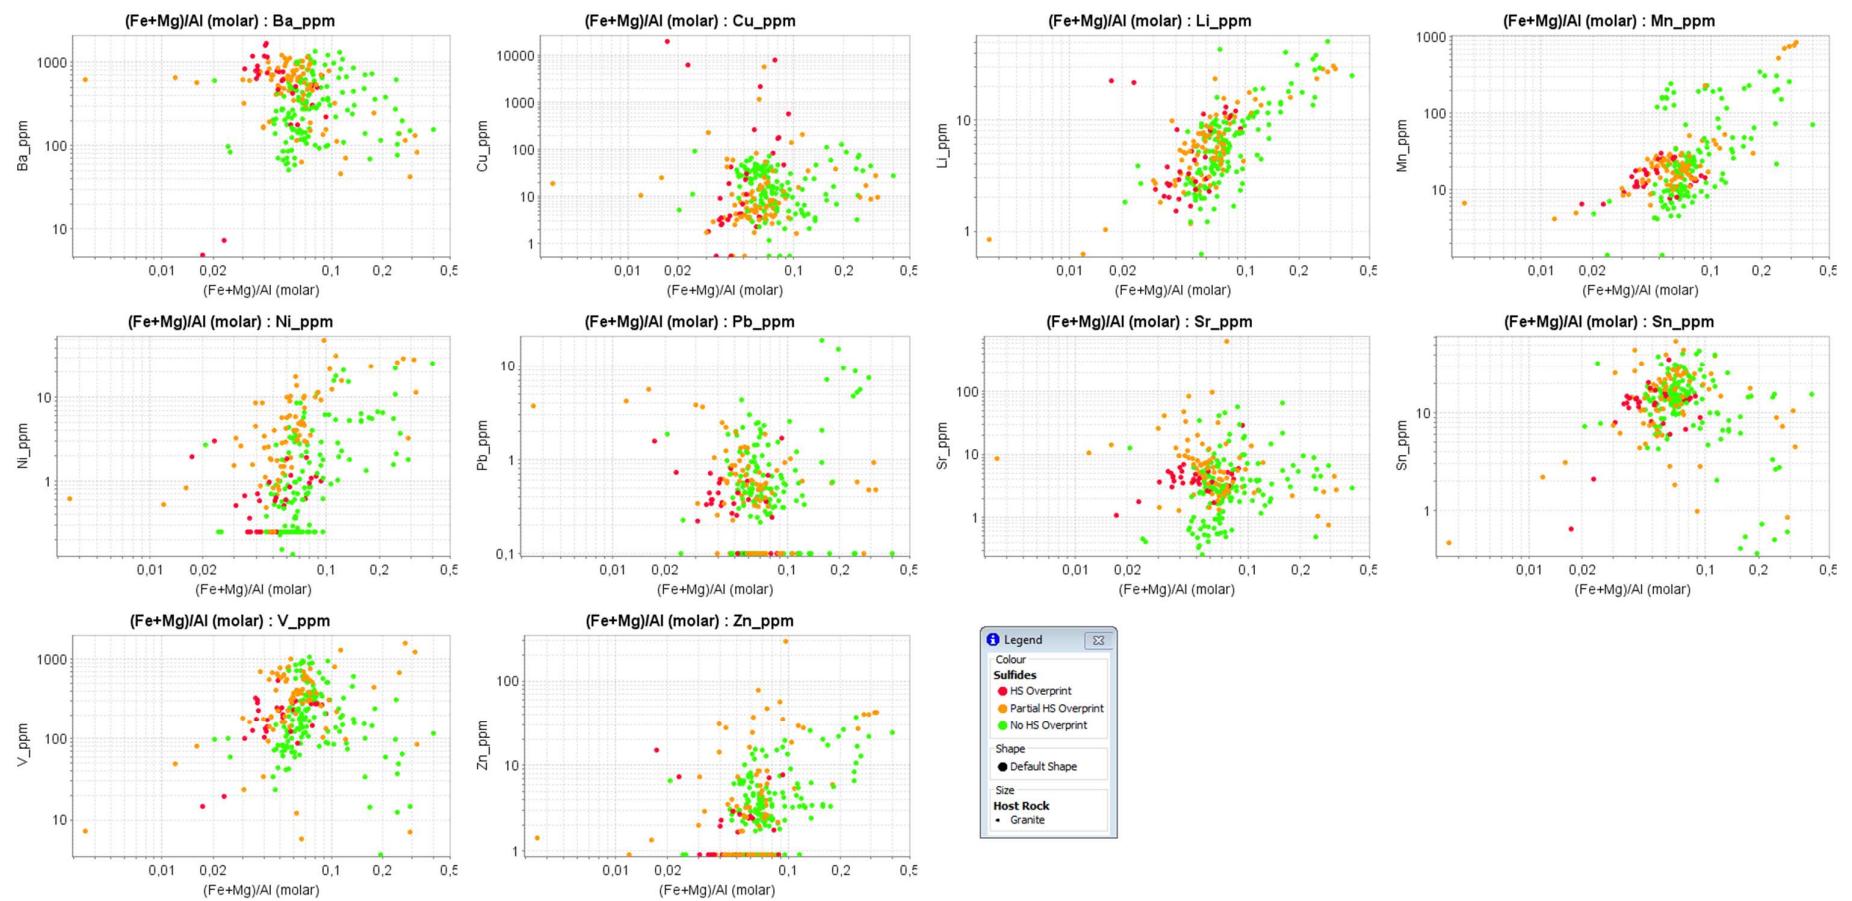

Figure 3.14: Effect of high sulfidation overprint on granite-hosted sericite trace element geochemistry. All data located in Appendix 2.

### 3.5 Apatite, Monazite and Xenotime Geochronology

The observations presented above of two distinct sericite populations place no constraints on the absolute timing of the two events. In the greater Taca Taca district there is a Permian high sulfidation epithermal alteration system (Taca Taca Alto) located ~5 kilometres northwest of the Oligocene intrusions at Taca Taca Bajo (Zappettini and Blasco, 1998). Reconnaissance geochronology was therefore undertaken to validate or discard the hypothesis that the two sericite generations reflect an Oligocene hydrothermal overprint superimposed on an older Permian alteration system (Appendix 3). Also, this part of the study could be used to further constrain geochemical zonation in apatite that might clarify possible overprints between potassic and phyllitic alteration. (e.g., Mao Mao et al., 2016)

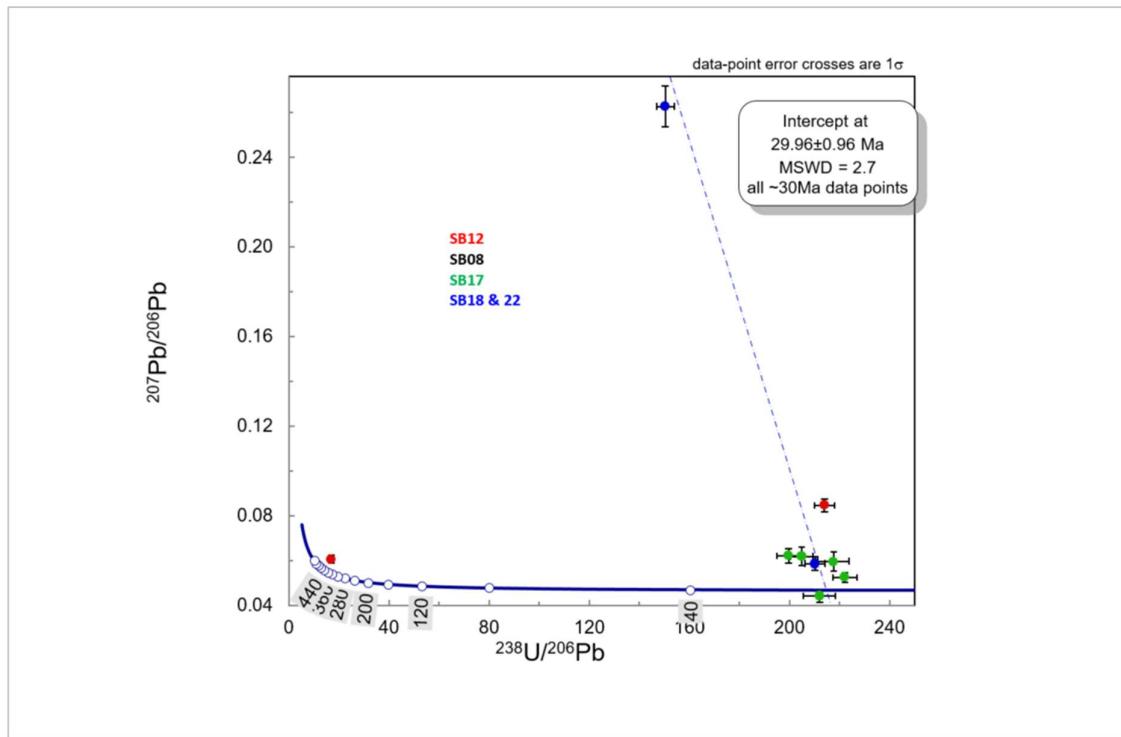

Figure 3.15: Concordia plot for monazite and xenotime U/Pb dating by LA-ICPMS. The data results in an average age of  $29.96 \pm 0.96$  Ma, reinforcing pre-existing dating that suggested the barren Oligocene porphyry as the causative intrusion of the alteration cell and mineralisation. All data located in Appendix 3.

Only one sample submitted for laser ablation analysis of apatite contained radiogenic Pb (TTB\_SB01, a background control sample), and technical issues with the LA-ICPMS analysis did not allow for robust results from apatite samples. Hydrothermal monazite and xenotime U-

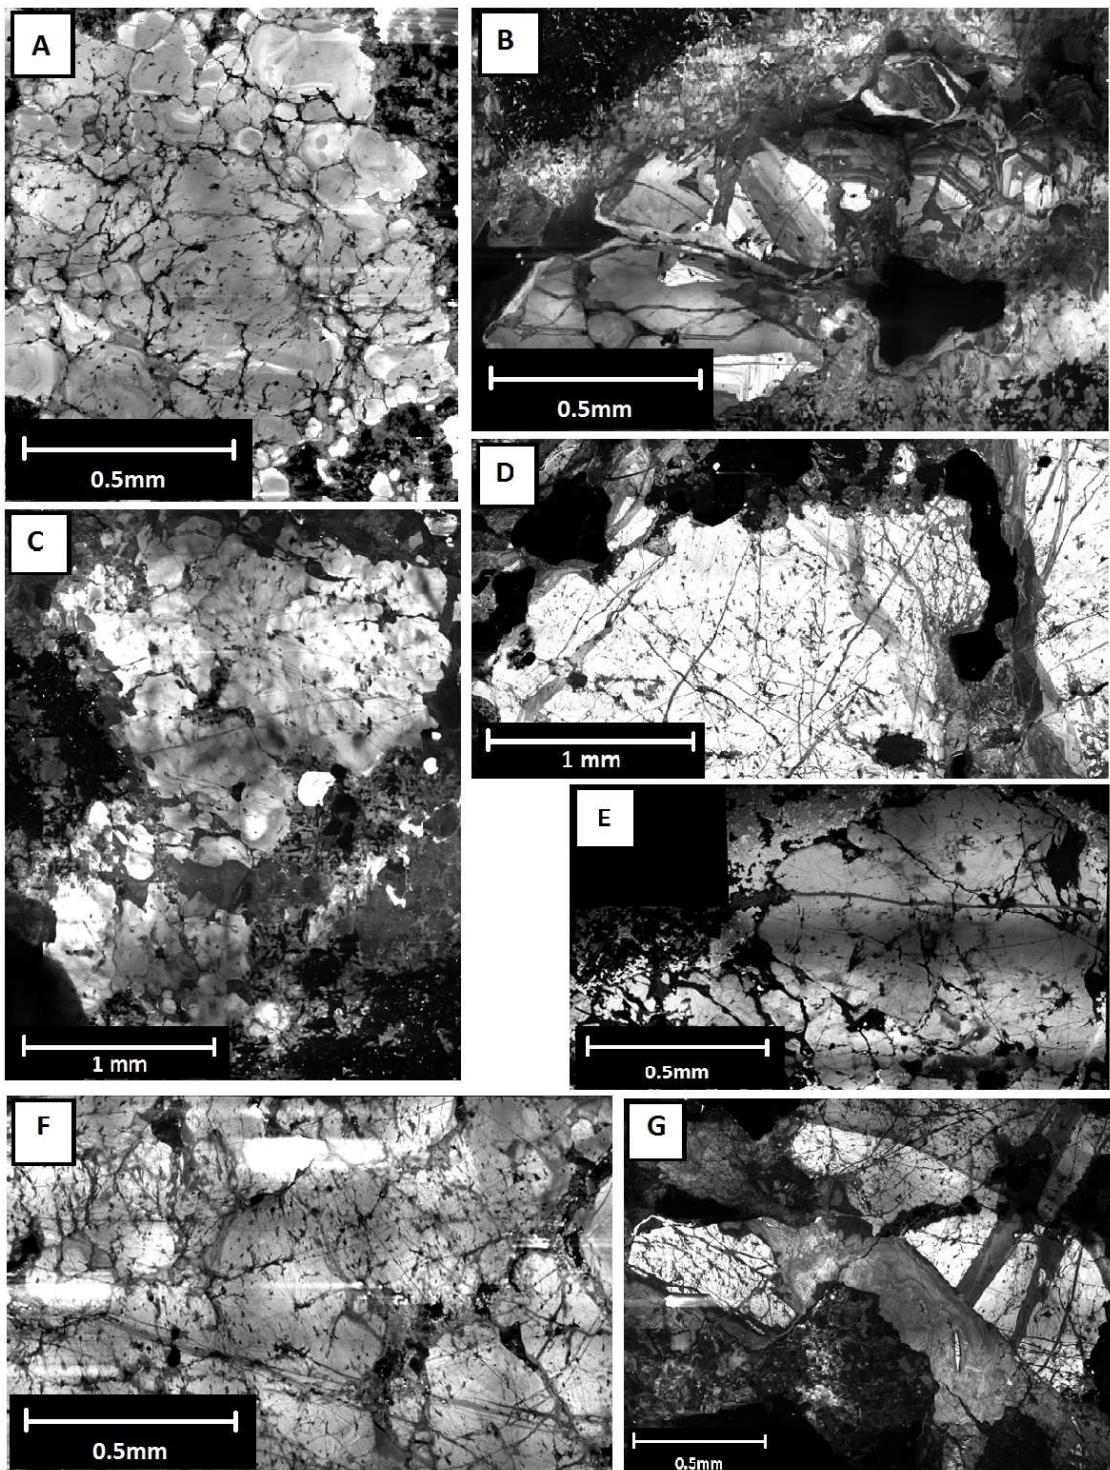

Pb geochronology successfully yielded a Concordia age of  $29.96 \pm 0.96$  Ma, within error of existing geochronological results for Taca Taca Bajo. There is no suggestion of pre-existing Permian hydrothermal phosphates or reset phosphates other than one Devonian xenotime grain that plausibly belongs to the Silurian granite emplacement and has been partially reset (Fig. 3.15). This result implies that either A) there is only one phase of hydrothermal alteration related to the rhyodacite porphyry at 30-29 Ma; or B) the Oligocene event completely reset all pre-existing alteration. In both cases, sericite geochemistry would not be affected by pre-existing events, and as there is no other evidence of the latter, interpretation of both sericite generations being products of the Oligocene hydrothermal activity is considered the simplest explanation.

### 3.6 Quartz Characterisation

Quartz CL images display common hydrothermal and magmatic textures. Isolated magmatic quartz grains from granite display as round, CL-bright features. These grains are overgrown by CL-grey quartz and are cut by CL-grey and CL-dark fractures (eg. TTB\_SB07). These overgrowths and fracture-filling of weakly to non-fluorescent quartz are interpreted as late, lower temperature and lower pressure quartz (by analogy with Rusk and Reed, 2002). Hydrothermal features observed are euhedral growth zones, CL-gray patches, CL-dark patches and streaks, healed fractures with non-luminescent intensity, cobweb-like networks and jigsaw puzzle pieces.

Several quartz types have been recognized at Taca Taca Bajo, and their sulfide affinities recorded (Fig. 3.16):

- Early stage, rounded, CL-bright, igneous quartz, observed in sample TTB\_SB07 and TTB\_SB18 (Fig. 3.16c,e).
- Coarse grained, CL-gray quartz with growth textures. This is seen in veins and as overgrowth to igneous quartz. It is commonly intergrown with chalcopyrite and minor pyrite. Pyrite in cracks and cavities within coarse grained quartz are common features. This can be observed in samples TTB\_SB07, TTB\_SB08, TTB\_14B, TTB\_SB17, TTB\_SB18, TTB\_SB19, TTB\_SB20, TTB\_SB22 and TTB\_SB24 (Fig. 3.16a,b,c,d,e,g).
- Coarse grained, isolated, CL-gray quartz associated with chalcopyrite, observed in sample TTB\_SB08 (Fig. 3.16b,d).

*Figure 3.16: Quartz CL images A) Fine grained quartz intergrown within quartz grains with associated pyrite; from TTB\_SB20, B) Coarse grained quartz with euhedral growth textures and associated chalcopyrite in vein; from TTB\_SB08, C) Isolated coarse grained, CL-gray quartz with chalcopyrite; from TTB\_SB08, D) CL-bright igneous quartz cut by CL-gray fine grained quartz. Pyrite associated to fine grained quartz in fractures; from TTB\_SB18, E) CL-gray, embayed quartz grain with CL-gray, fine grained quartz intermixed with sericite and disseminated chalcopyrite; from TTB\_SB13, F) Coarse, CL-gray quartz cut by darker CL quartz fractures and rimmed with dissolution textures. Pyrite and chalcopyrite intergrown with coarse grained quartz; from TTB\_SB24, G) CL-bright coarse grained quartz with dissolution, overgrowths and fractures of CL-gray quartz associated with py; from TTB\_SB18*

- Fine grained CL-gray quartz associated with sericite and chalcopyrite and/or pyrite. This can be seen in TTB\_SB13, TTB\_SB17, TTB\_SB18, TTB\_SB20 and TTB\_SB20 (Fig. 3.16a,c,e,f).
- Fine grained CL-gray quartz cutting through all previous quartz as fracture fill, this can be observed in sample TTB\_SB24 (Fig 3.16g).

At least 4 stages of quartz growth and dissolution can be recognized. These follow a simple cooling pattern from CL-bright cores to later darker CL features. This observation suggests that a simple paragenesis from hotter fluids at higher pressure to cooler fluids at lower pressure through time is applicable and no overprinting systems are interpreted.

### 3.6 Phyllitic Overprint on Potassic alteration

Potassium staining was done on all samples to study the degree of relict potassic alteration on the granitic batholith prior to the sericitic overprint and its relationship to ore grade mineralisation. Background samples of granite (TTB\_SB01, TTB\_SB02, TTB\_SB03) provided visual identification of igneous orthoclase contents in the unaltered granite host (Fig. 3.17). Samples with predominant muscovite-pyrite assemblages, either from the outer phyllitic halo or due to very strong overprint of the muscovite-high sulfidation assemblage, contain minor or no relict orthoclase. This alteration destroyed feldspar and can be observed in TTB\_SB11, TTB\_SB12, TTB\_SB13 and TTB\_SB18 (Fig. 3.18). Samples with predominant phengite-chalcopyrite assemblages show moderate to intense relict orthoclase flooding that was overprinted by sericitic alteration. This can be observed in samples TTB\_SB08, TTB\_SB09, TTB\_SB10, TTB\_SB17, TTB\_SB22 and TB\_SB24 (Fig.3.19). These observations suggest an intimate spatial relationship between potassic alteration, ore deposition and phengitic alteration.

## 4. Interpretation and Discussion

### 4.1 Alteration Paragenesis

The data presented in this study support pre-existing interpretations which suggested that all of the hydrothermal alteration at Taca Taca Bajo formed during the early Oligocene. These results are consistent with the interpretation that the Oligocene rhyodacite porphyry phases emplaced at this time were causative to the hydrothermal alteration. Molybdenite Re/Os dating ( $29 \pm 0.2$  Ma, Gigola, 2008) also suggests that mineralisation was related to this magmatic - hydrothermal event. The causative intrusives have undergone intense potassic alteration, with fine grained, pervasive, shreedy biotite replacing the groundmass, and have been cut by a barren quartz vein stockwork (e.g. Fig. 3.2d-f). The spatial dislocation between the potassic core and Cu mineralisation described by Waechter (2016) is interpreted following the scheme of Proffett (2009) as evidence that Taca Taca Bajo was emplaced relatively deep by comparison with classical porphyry systems (>5 km). The hydrothermal assemblage is therefore inferred to have been driven by reactions between wallrock and a single phase, low salinity magmatic fluid.

Background samples show only minor disseminated chalcopyrite in the biotite-rich groundmass of the rhyodacite porphyry dykes, although this scarcely causes enrichment at the scale of assay intervals. Potassic alteration in the granite adjacent to the causative intrusions is characterised by strong orthoclase flooding and secondary biotite replacing primary ferromagnesian minerals, together with barren quartz veins (e.g. Fig 3.19).

The potassic-altered granite has been overprinted by phyllitic alteration. The early stages of phyllitic alteration are characterised by quartz-chalcopyrite veins with phengite selvages, which commonly overlap to yield near-pervasive phengite alteration (e.g. Fig. 3.3). Within the selvages, phengite has replaced pre-existing biotite-altered ferromagnesian sites and occurs in the orthoclase altered matrix. There is a strong positive correlation between disseminated or patchy chalcopyrite and phengite alteration in the wall rock. The mineralisation style is typical of potassic and sericite-chlorite-clay (SCC) type alteration in that Cu sulfide deposition occurs in the selvage of veins, rather than exclusively within the vein fill (Rusk et al., 2008; Sillitoe, 2010). This suggests two non-exclusive possibilities: A) the patchy, disseminated

chalcopyrite was deposited during potassic alteration and survived the phengite overprint; or B) the phengite event marks the transition from potassic to phyllitic alteration, analogous to SCC alteration although with a different composition, and copper was introduced during this stage. The variation in composition is potentially due to the bulk felsic composition of the wallrocks, where the abundant K and scarce Fe would favour phengite formation over chlorite. Chalcopyrite also occurs in thin, rectilinear quartz veins with phengite haloes that overprint potassic alteration (e.g. Fig 3.3b). This observation demands that at least some chalcopyrite was introduced during the phengitic event. Exactly when copper was added as disseminated, patchy chalcopyrite that coexists with fine grained, shaggy phengite that replaced ferromagnesian sites (e.g. Fig. 3.7g) cannot be resolved between the potassic and phengite events. Spectral data (Fig. 3.10) suggests that the fluids that produced phengite-dominated green sericite alteration were less acidic than those that produced later white sericite, supporting the idea that phengite alteration formed during the transition from potassic to phyllitic alteration.

Textures observed in the SEM backscattered electron images (Fig. 3.7) suggest that phengite replaced biotite and, to a lesser degree, orthoclase in the granite. This is consistent with the LA-ICPMS data, where phengite samples follow biotite and orthoclase compositional trends rather than pure phengite trends in CMKB diagrams (Fig. 3.9). The trace element composition of the phengite therefore permits an interpretation that Fe, Mg, K contamination of the sericite occurred by inheritance from pre-existing minerals. Phengitic alteration is also observed as selvages to CL-grey quartz (with growth textures) ± chalcopyrite veins, which confirms that chalcopyrite was also deposited at least partly independent of replacement reactions during phengite alteration.

Textural relationships (Fig. 3.7) and phyllosilicate variation between muscovite and phengite suggest a paragenetically later overprint of phengite by low-pH fluids (main phyllitic phase; Fig. 3.10) that destroyed the original rock texture and replaced the pre-existing secondary mineral assemblage with muscovite.

Whereas the phengitic phyllitic alteration was either copper-additive or at the very least not ore-destructive, the more acidic muscovite alteration caused partial to full replacement of chalcopyrite by pyrite (ore destruction). This relationship is seen in the hand lens scale, as

well as at the microscopic scale (Fig. 3.6). Where muscovite alteration is weaker or appears transitional from phengite alteration, ore minerals and phengite are still fully or partially preserved, explaining the spatial relationship between Cu grades and phengite occurrence.

The high sulfidation assemblage of pyrite, bornite, chalcocite ± covellite, digenite is intimately associated with muscovite, and relates to the late stages of phyllitic alteration. Quartz CL imaging records a general down-temperature path during hydrothermal quartz deposition. The hydrothermal cell is therefore interpreted to have become more acidic upon cooling, with a concomitant increase in the sulfidation state (Fig. 1.2; e.g., Sillitoe, 2010). The strong relationship between muscovite and high sulfidation assemblage suggests that the silicate and sulfide assemblages record alteration by a single fluid. Where this fluid encountered chalcopyrite, it was initially replaced by the high sulfidation assemblage, and upon continued alteration Cu was remobilised and removed. This change in sulfidation state is transitional and associated to the intensity of the late stages of the hydrothermal paragenesis. The original paragenetic sequence presented by Almandoz (2008), has therefore only been slightly modified to reflect the variations presented in this study (Fig. 4.1).

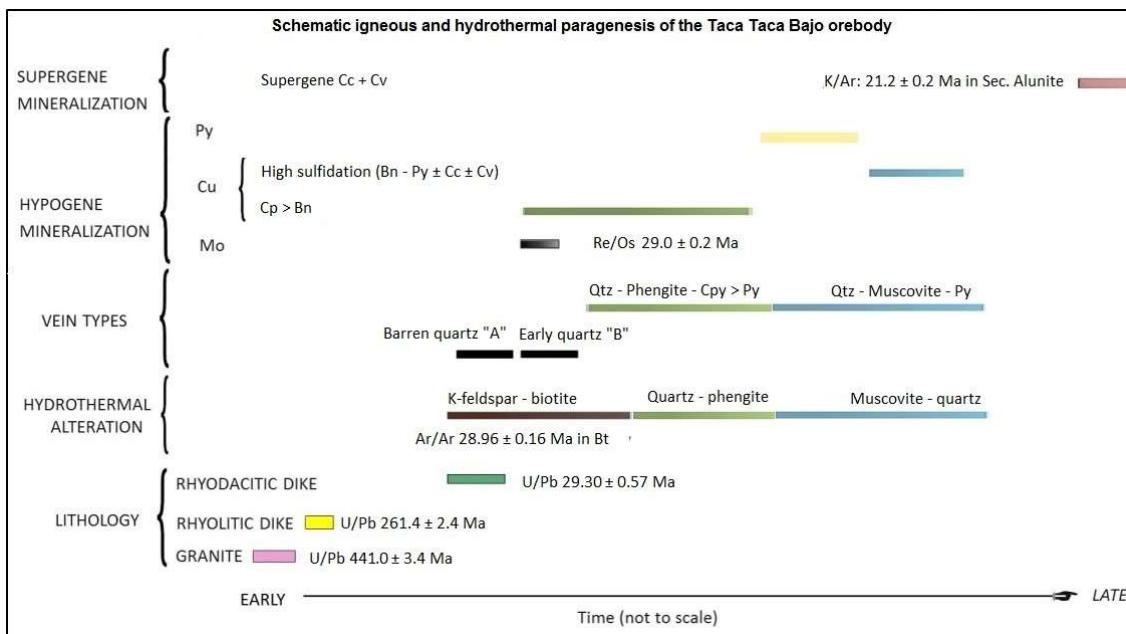

Figure 4.1: Proposed paragenesis of the Taca Taca Bajo orebody (Modified after Almandoz, 2008). Cc = chalcocite, Cv = covellite, Py = pyrite, Mo = molybdenite, Bn = bornite, Cpy = chalcopyrite, Qtz = quartz.

## 4.2 Deposit scale integration

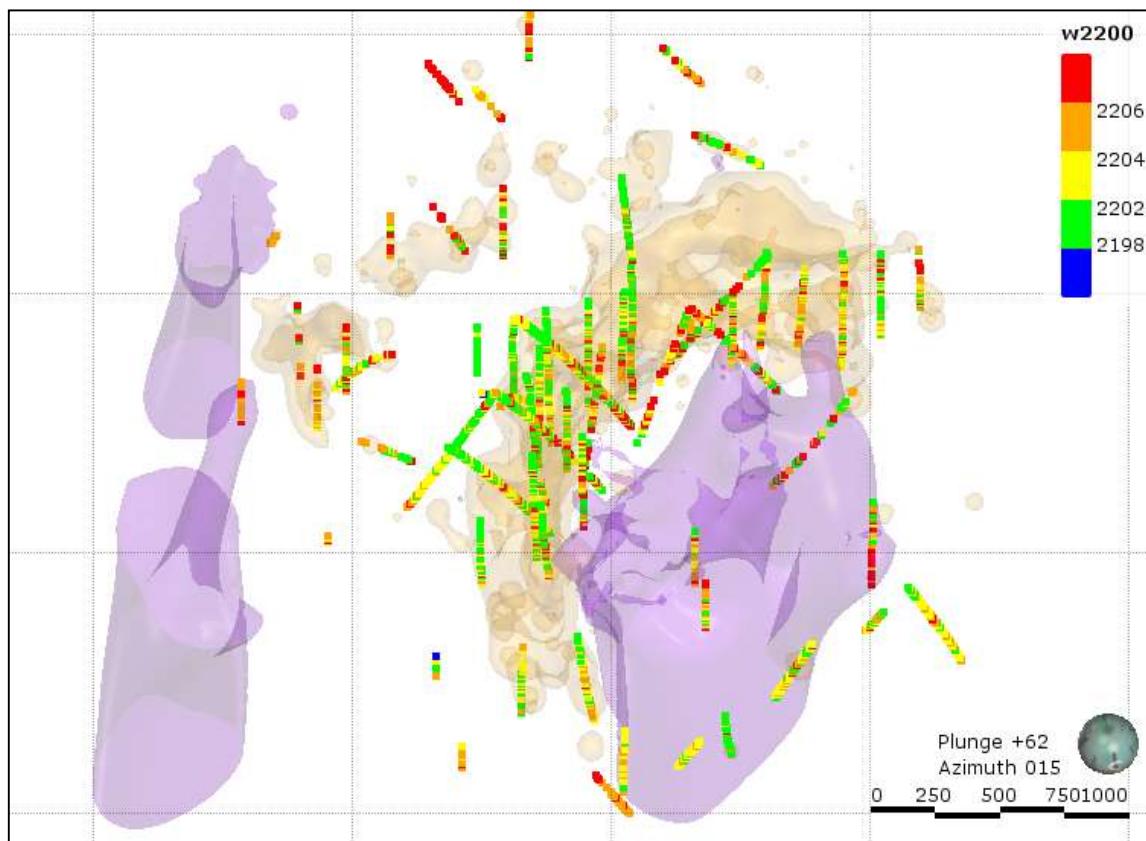

The detailed petrographic and microanalytical results presented here permit some extrapolation to the deposit as a whole. The best data for this purpose is the Terraspec ASD data collected by FQM geologists in 2014, as this is a deposit-wide dataset but the spectrometer has a limited field of view and hence partly avoids possible issues related to whole-rock contamination. For the spectrometry to be considered representative a large quantity of data is required. The dataset at Taca Taca Bajo comprises downhole data from 68 drill holes from in and around the 0.25% Cu shell, along which spectra were collected every 2m.

Considering only the sericite-bearing samples, the w2200 scalar (sericite composition) shows a clear trend from longer wavelength within the 0.25% Cu grade shells, to shorter wavelengths in the more distal zones of the ore zone and into the pyritic shell (Fig. 4.2). The results of this study suggest that that the high wavelength sericite samples are phengite. The distribution of phyllosilicates with the spectral character of phengite could therefore be interpreted to mark the minimum original volume of potassic alteration prior to phyllitic overprint, as phengite is observed to nucleate on secondary biotite and orthoclase flooded granite. The spectral zonation is opposite to the model suggested by Halley et al. (2015), but in detail does not contradict that model, as the w2200 wavelength shift is due to a change of mineral composition, rather than variations within the same mineral species. Nonetheless, the recognition of ‘inverse’ w2200 zonation among the greater group of pale phyllosilicate minerals is relevant to exploration for porphyry deposits.

The variability observed in the microscopic scale can also be observed in the deposit scale, where the phengite domain also incorporates muscovite samples. This is due both to the overprinting nature of phengitic and muscovitic alteration and to the limitations of interval spectral sampling. On both drill core and laser mounts, it is observed that muscovite and sericite commonly coexist, which is due to variable intensity of the overprint by muscovite. This relationship is also observed in the deposit scale, though phengite is dominant adjacent to the rhyodacite porphyry stock and muscovite is dominant outside the 0.25% Cu grade shell.

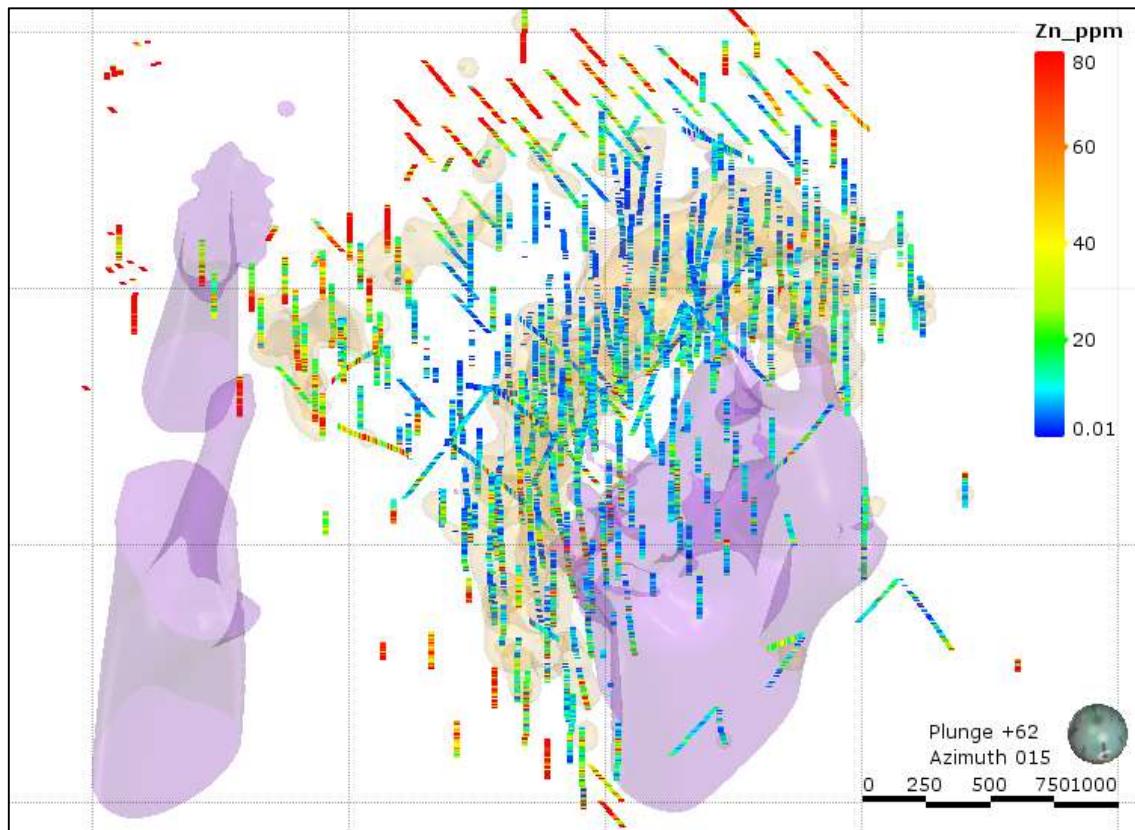

The application of whole rock trace element data to extrapolation from the microscopic to deposit scale has some limitations due to the more diverse mineralogy present in a 2-meter-

wide assay interval, than in targeted microanalysis. This extrapolation is worthwhile, however, as the continuity of the assay database permits a more representative interpretation than the 68 drill holes for which spectral measurements are available. Whole rock Cu and Zn show recognisable patterns at a deposit scale that are also observable on LA-ICPMS phyllosilicate chemistry and petrographic data. At the deposit scale, there is a positive correlation between phengite - chalcopyrite domains and Zn values at trace levels (e.g., Figs. 3.12 and 3.13). Far stronger Zn enrichment occurs on the periphery of the deposit, but there is a region of minor Zn enrichment coincident with the phengite - chalcopyrite ore zone (Fig. 4.3). This could be due to Zn substitution into the chalcopyrite lattice, or to fine sphalerite accompanying this assemblage, although the latter seems unlikely as it has not been observed.

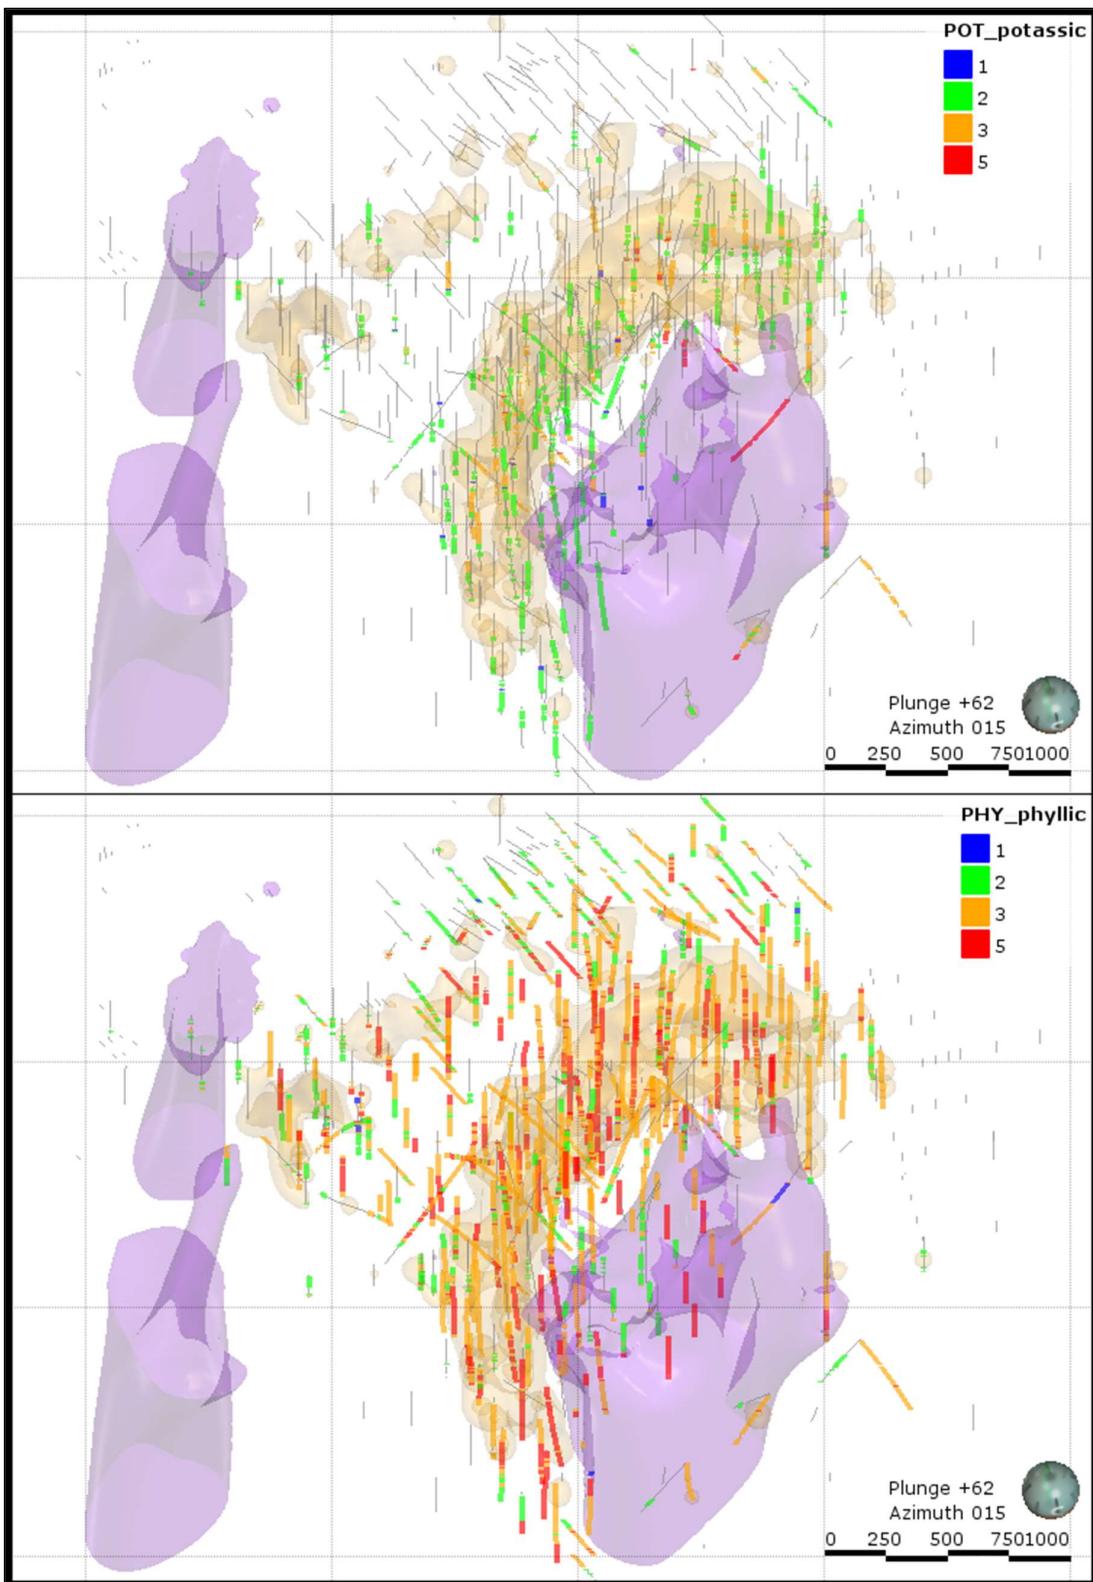

*Figure 4.2: Deposit scale view of w2200 (sericite composition) scalar on Terraspec ASD data. Higher wavelength values interpreted to be the extent of phengite, marking the minimum extent of phengite overprint on potassic alteration. Note the same proximal characteristics are observed on small satellite bodies NW from the main ore zone.*

Alteration logs provided by FQM were revised to evaluate the extent of potassic and phyllitic alteration. Potassic alteration has been recognised in varying intensities, not only in the barren rhyodacite porphyry stocks, but within the main orebody and also in the satellite orebodies roughly 750 metres northwest of central Taca Taca Bajo (Fig. 4.4a). No significant relict potassic alteration has been observed outward of the main orebody (i.e. in the pyritic halo). In contrast, phyllitic alteration has been logged throughout the whole deposit, except for the barren core in the rhyodacite porphyry (Fig. 4.4b). This original logging includes phengite and muscovite alteration, hence it does not discriminate between the ore zone and the pyritic halo, and in fact efforts to log the two separately failed to reveal systematic zonation patterns.

*Figure 4.3: Zn enrichment in Taca Taca Bajo assay data. Strong enrichment is peripheral to the deposit, but a trace level enrichment is observed in the phengite-chalcopyrite domain within the orebody.*

The logged alteration observations, together with the current interpretation of phyllitic alteration overprinting potassic alteration and the modelling of phengite alteration from ASD and assay data, allows an interpretation of the spatial distribution of the main paragenetic stages described above. Potassic alteration extends well into the orebody and is entirely

*Figure 4.4: Logged alteration shown in comparison with 0.25% Cu shell (orange) and modelled rhyodacite porphyry stock (purple). All data provided by FQM. A) Logged potassic alteration coloured by intensity (1-5). B) Logged phyllitic alteration (bulking muscovite and phengite alteration), coloured by intensity (1-5).*

contained within the pan view envelope of later muscovite, such that these two alteration minerals have a near concentric distribution (Fig. 4.5). In contrast, phengite overprints potassic alteration only in the N and W quadrants. As the distribution of phengite more closely mimics Cu distribution than the primary potassic alteration distribution, it is likely that Cu introduction occurred mostly during the phengite stage.

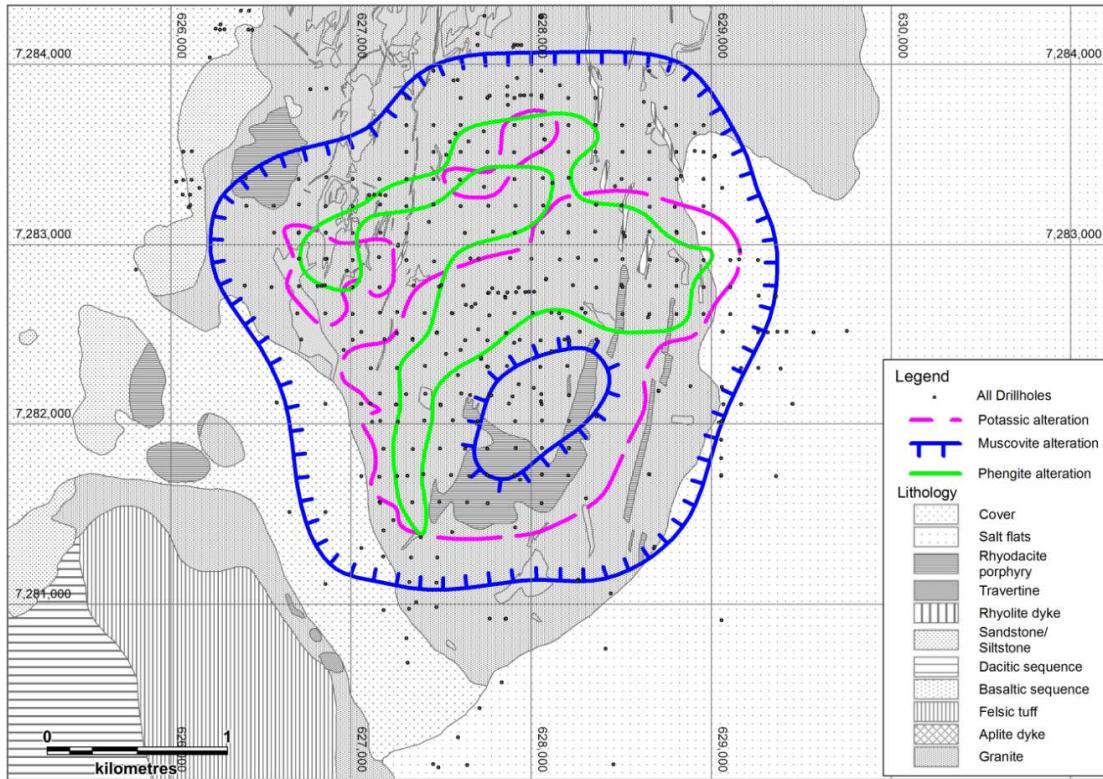

Figure 4.5: Surface projection of the potassic, phengitic and muscovitic alteration overlain on surface geology from Wood et al. (2015).

### 4.3 Implications for porphyry ore formation

As described in Chapter 1, phengitic alteration is typically seen as an outer domain to muscovitic alteration, with which it is commonly grouped in a generalised phyllitic assemblage (John et al., 2010). Green mica, comprising coexisting chlorite and illite intimately associated with Cu sulfides and potassic alteration is considered part of the SCC alteration assemblage; a transitional phase from potassic to phyllitic alteration developed at the higher levels of some porphyry Cu-Au deposits (Sillitoe, 2010). At Taca Taca Bajo, the green mica is phengite rather

than chlorite-sericite, although it is intimately associated with Cu sulfides and potassic alteration as a transitional alteration facies. Alteration at TTB therefore does not fit comfortably into the current porphyry model, although Ossandon (2001) described green micas associated to ore in a similar paragenetic and textural context at Chuquicamata, Chile, raising the possibility that this facies is not unique to TTB. Further understanding of this feature will require studies in different deposits to make analogies and to understand the genetic implications of this feature in porphyry Cu systems.

White mica chemistry and stability in porphyry systems is influenced by temperature and acidity, although it may also be affected by the increased pressure or bulk rock composition, analogous to chlorite supplanting illite at high Fe activity (e.g., Parry et al., 1984; Guidotti and Sassi, 1998; Sassi et al., 1994; Seedorf et al., 2005; Halley et al., 2015).

The author is unaware of any studies that have specifically addressed this variety of controls on potassic white mica mineralogies and compositions outside of the metamorphic environment, i.e. at conditions relevant to porphyry copper alteration systems. However, some constraints are possible on the conditions of formation of the Taca Taca Bajo system. The pale phyllosilicates are almost uniformly properly ordered micas, and correspondingly, illite and smectite are scarce. Therefore, the temperature of formation of both the phengite and muscovite stages is above the thermal threshold for illite stability (Meunier and Velde, 2004). This is consistent with interpretations that envisage formation of the Taca Taca Bajo alteration system at greater depth than classical porphyry copper systems. Why phengite is so abundant at Taca Taca Bajo, and is so closely related to copper distribution remains unexplained, but it is easy to imagine future studies that either a) consider phyllosilicate composition and mineralogy at a range of relevant pressures and bulk compositions, or b) compare the deep hypogene paragenesis of various porphyry Cu deposits emplaced into felsic host rocks, such as parts of Collahuasi, Chile, hosted by Permian rhyolitic strata, or several of the deposits in SW Arizona emplaced into Mesoproterozoic A-type granites.

#### 4.4 Exploration Implications

Characterising, and recognising the variation among porphyry Cu alteration and mineralisation facies is fundamental for successful exploration. Despite a series of well-documented similarities, every porphyry deposit is different in some way, so making analogies between field observations and recognised patterns elsewhere is important in the correct interpretation of limited exploration data.

Taca Taca Bajo is a rare example of a porphyry copper deposit with abundant phengite alteration directly associated with hypogene mineralisation. Exploration models for porphyry copper deposits therefore must permit the occurrence of phengite as a transitional phase between potassic and muscovitic phyllitic alteration, as well as the more conventional description of this mineral as a distal expression of phyllitic alteration. At Taca Taca Bajo, the phengitic stage overprints the outer potassic alteration with an asymmetric distribution, and hence the permeability controls on phengite distribution are inferred to be the primary control on grade distribution. Phengite alteration did not develop in a central ‘core’ of potassic alteration and abundant early quartz veins, and is only weakly developed on the S and E quadrants of the greater potassic alteration domain. At the level of present exposure there is no sense that the phengite stage at TTB is some relict of a shallow analogue of potassic alteration akin to SCC alteration, but instead forms part of a distinct lateral zonation pattern (Fig. 4.5).

Further studies in similar deposits need to be carried out to better understand the relationships between magmatic hydrothermal processes and their mineralogical manifestations, i.e., whether this style of alteration is a persistent feature of deeply emplaced porphyry copper systems in which alteration is mostly caused by a single-phase moderately saline fluid. Conventional fluid inclusion petrography studies, investigation of the inclusion chemistry, and titanium geothermometry on quartz (e.g. Huang and Audétat, 2012) in the different hydrothermal phases documented in this study may provide further constraints on the processes related to development of Taca Taca Bajo and comparable mineral deposits. I hope that those constraints prove useful to explorers looking to recognize and delineate similar systems.
